Obesity (BMI >30)	2 818	8.3	4.8	11.7	6 027	4.7	2.5	6.9

[a]Based on body mass index (BMI), which is defined as weight in kilograms divided by height in square meters (kg/m²).

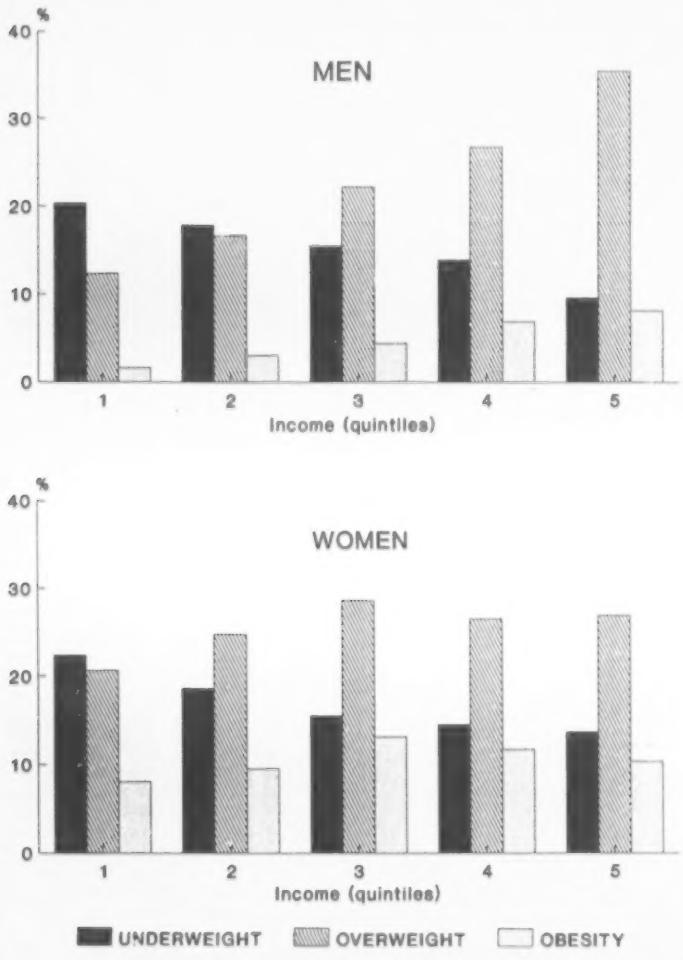

FIGURE 1—Age-adjusted prevalence (%) of underweight (body mass index [BMI] < 20 kg/m²) and overweight/obesity (BMI ≥ 25 kg/m²), by income and sex: Brazil, 1989.

that budget. Family income was categorized into quintiles and also as being above or below twice the Brazilian minimum wage per month (US $150 in July 1989), the estimated income necessary for the survival of a family of four.

Analytical Procedures

Body mass index, defined as weight in kilograms divided by height in square meters (kg/m²), was classified according to standards of the World Health Organization (WHO)[8] with a modification in terminology. Underweight was defined as a body mass index of less than 20 kg/m², normal weight as 20 to 24 kg/m², overweight as 25 to 30 kg/m² (WHO obesity grade 1), and obesity as above 30 kg/m² (WHO obesity grades 2 and 3). The overweight and obesity categories were combined since findings for these two categories were very similar. Persons missing data were excluded; there were 115 missing values for body mass index and 800 missing values for income in the 1989 survey.

The SUDAAN DESCRIPT procedure[9] was used to estimate the population percentages of underweight, overweight, and obesity, age-standardized by 10-year age groups to the estimated Brazilian population in 1989. Logistic regression with RTILOGIT[10] was used to examine the age, sex, and income-adjusted associations of underweight and overweight/obesity with urban or rural residence and geographic region of the country. These regions were entered in the models as four indicator variables, with the Southeast being the reference region.

Brazilian prevalence of overweight/obesity (body mass index ≥ 25 kg/m²) was compared with prevalences for Great Britain in 1980,[11] Canada in 1981,[11] and United States from 1976 to 1980.[12]

Results

Only 45.7% of women and 57.1% of men were classified as having normal weight in the 1989 survey. In the 1974/75 survey, underweight was more prevalent than overweight/obesity, but by 1989 the reverse was the case (Table 1).

Prevalence of Underweight

The overall prevalence of underweight was 16.0%, with 13 million Brazilian adults classified as underweight in 1989. Overall prevalence was slightly higher among women than among men (Table 1). For both sexes, the age-adjusted prevalence was higher in rural than in urban areas (Table 2). The highest prevalence of underweight was found in the Northeast and the lowest was in the South. For both sexes, the prevalence of underweight decreased with increasing income (Figure 1).

In the multivariate logistic regression analysis, age, income, sex, rural residence, and geographic region were significant independent risk factors for underweight (Table 3). Living in the South, living in a urban area, and being relatively affluent decreased the odds of being underweight.

Prevalence of Overweight and Obesity

The overall prevalence of overweight/obesity in 1989 was 32.8%. Women had a greater prevalence of overweight/obesity than men (Table 1). Among men, the prevalence was much higher in urban than in rural areas, whereas among women, a clearly higher urban prevalence occurred only in the Northeast and the Southeast (Table 2). Among the regions, the highest prevalence of overweight/obesity was found in the South and the lowest was in the Northeast.

Prevalence of overweight/obesity increased with income among men but did not increase beyond the third quintile of income among women (Figure 1). In the logistic regression analysis, all variables studied were significantly associated with overweight/obesity, with associations opposite to those found with underweight (Table 3). The only exception was that women were at higher risk than men of both underweight and overweight/obesity.

Trends in Body Mass Index in Brazil

The trend for the 15-year period studied was a striking reduction in the prevalence of underweight and an increase in the prevalence of overweight/obesity (Figure 2). Decrease in the prevalence of underweight was about 36% for both sexes combined. For men, overweight increased by 56.3% and obesity increased by 92.0% whereas for women, the increases were less pronounced: 39.7% for overweight and 69.6% for obesity (Table 1).

International Comparisons

The overall prevalence of overweight/obesity among men in Brazil was much lower than that in some developed countries (Figure 3). However, when the analysis was restricted to Brazilian men

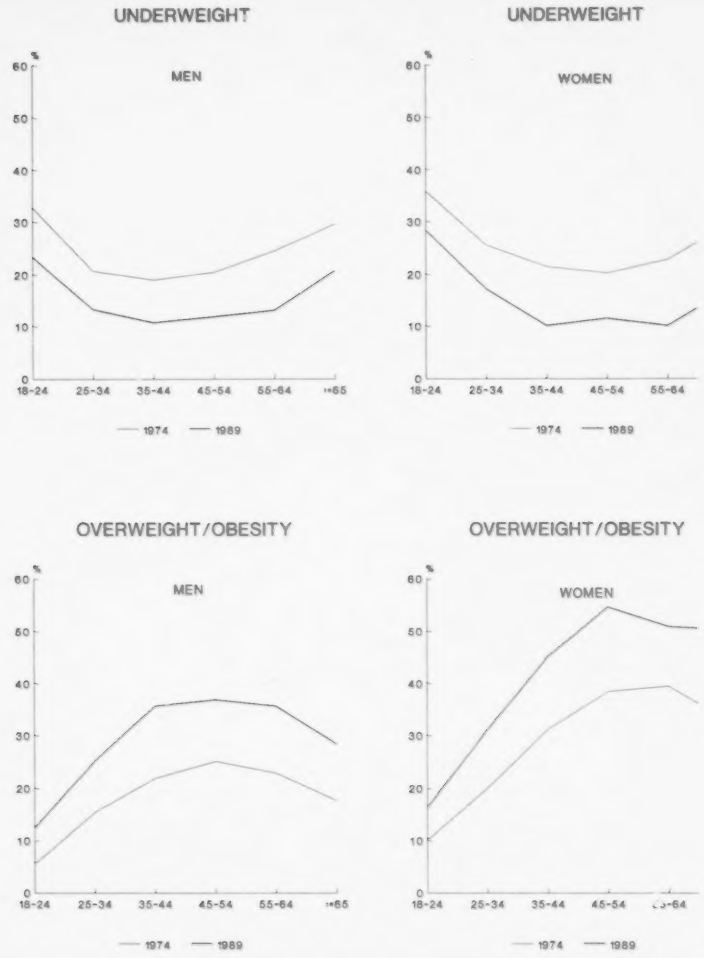

FIGURE 2—Prevalence (%) of underweight (body mass index < 20 kg/m²) and overweight/obesity (BMI ≥ 25 kg/m²) in two surveys—Estudo Nacional de Despesa Familiar, 1974/75, and Pesquisa Nacional de Saúde e Nutrição, 1989—by sex.

with family income higher than twice the Brazilian minimum wage, the prevalence of overweight/obesity was comparable to that in the other countries. Among women, the prevalence of overweight/obesity, both overall as well as among those with higher income, was comparable to that among US women and higher than that in the other countries.

Discussion

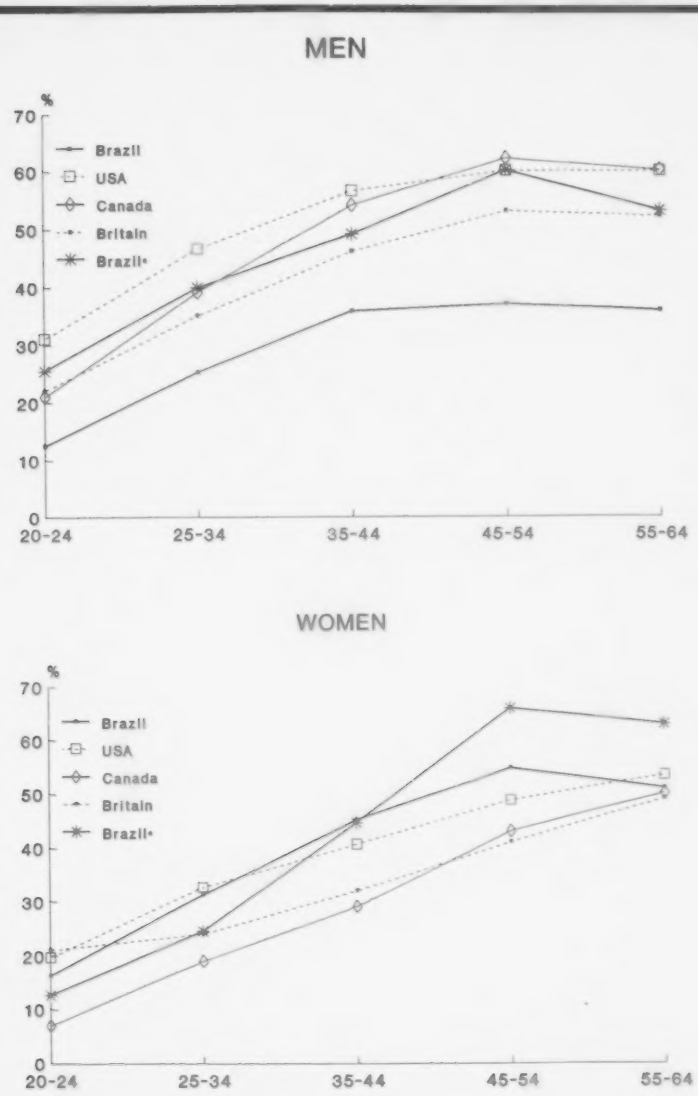
There was a striking difference in body mass index in Brazil according to sex, region, urbanization, and income. Women were almost 2.5 times as likely as men to be obese, a degree of gender difference unobserved in developed countries (Figure 3). However, the pattern in Brazil may be changing toward that of these other countries. The prevalence of overweight/obesity increased more rapidly for men than for women between the two surveys, and the greatest increase was among young men. Also, at the highest income levels, the prevalence of overweight was more common among men than among women. These shifts toward the attributes of more developed countries raise the possibility that Brazil is currently in the midst of changes that occurred among more economically developed countries before population-based surveys were in general use. A stepwise increase of overweight/obesity with income was observed for men, whereas other studies have found weakly positive associations.[13,14] In contrast, a negative association between socioeconomic status and body mass index has been reported in many studies of women.[15–17] Among Brazilian women, the prevalence of overweight/obesity was highest in the third quintile of income and slightly lower for the two higher quintiles.

Both urbanization and the more developed geographic regions in Brazil were positively associated with the prevalence of overweight/obesity and negatively associated with the prevalence of underweight, independently of income (Table 3). Additional adjustment for race did not explain these urban/rural and regional differences. Comparative data on race are not available for the 1974/75 survey.

The striking variations in body mass index by urbanization, income, and region of the country indicate that environmental factors are important determinants of obesity. Both the available supply of goods and services in urban areas and the nutritional status of the urban populations are better, as evidenced by greater mean heights among urban residents.[18] Chronic malnutrition and acute diarrheal illness in areas of poorer sanitation may also have contributed to regional and urban/rural differences in underweight.

The marked increase in the prevalence of obesity in a short space of time, as shown in this study, has not been observed in developed countries.[19–21] Our analysis supports the concept proposed by Price et al.[21] in 1991 that a general improvement in environmental conditions that predisposed all individuals to obesity would shift the overall body mass index distribution to higher values. However, the recent secular trends in developed countries have shown only an increase in the overweight component of the body mass index distribution without a substantial increase in the mean or median.[19,21]

Measures of stature and weight were carefully performed in both surveys; thus, the differences in body mass index between surveys are unlikely to be a result of inaccurate anthropometric measures. Moreover, any misclassification of body mass index would have been expected in both surveys since the measurement of weight and stature in both surveys was



Note. Brazilian curves marked with stars excluded the population below the poverty level (two minimum wages per month per family).

FIGURE 3—Prevalence (%) of overweight/obesity (body mass index ≥ 25 kg/m²) for Great Britain in 1980,[11] Canada in 1981,[11] United States from 1976 to 1980,[12] and Brazil in 1989.

very similar. Comparisons among countries also should not depend on methodological differences between surveys since all data were based on carefully measured weight and stature.

Differences in energy intake and physical activity are the obvious explanation for Brazil's rapid changes and geographic variations in the prevalence of overweight and obesity. Dietary data collected in the 1974/75 survey show a positive relationship of mean energy intake with both body weight and income.[22] Thus, part of the increase in body mass index in Brazil may be related to increased energy intake. However, even when controlling for income, a correlate of energy intake, marked urban/rural differences in body mass index persist. Perhaps greater physical activity is a reason for the lower risk of overweight and obesity in rural areas where manual labor remains common.

The rapid increase and wide demographic variation in the prevalence of overweight/obesity in Brazil present opportunities for studying the development of this condition. Such opportunities are not available in countries with slower anthropometric changes and less distinct demographic variations. □

Call for Abstracts for Second International Conference on Dietary Assessment Methods

The Second International Conference on Dietary Assessment Methods will be held in Boston, Mass, January 22 through 24, 1995. The conference is designed to facilitate ongoing exchange of information, stimulate national and international collaborative research, and encourage innovative approaches to improving methods for collecting and analyzing dietary data. This international exchange of knowledge and ideas will enhance our understanding of the role of diet in the etiology and prevention of disease and will facilitate the development of nutrition programs and policies leading to improved world health.

Participants will come from academic and health care settings, food industries, and government agencies around the world. Speakers and faculty will include a broad spectrum of internationally recognized experts in dietary assessment methodologies. This conference will provide opportunities to discuss subjects that include the cognitive influence in dietary assessment methodology, experiences from diverse cultures, food consumption patterns, biomarkers of dietary intake, calibration/validation methodology, statistical interpretation and adjustment of dietary data, surveillance and monitoring, and food composition/contaminants/xenobiotics.

The abstract submission deadline is July 15, 1994. Abstracts must pertain to one of the following seven program areas: recent advances in dietary assessment tools; recent advances in the evaluation of assessment methods; new approaches to assessing diets of diverse populations; advances in the evaluation and validity of specific food components; advances in methodological issues in the use of international data sets; advances in evaluating and interpreting dietary data; and the evaluation of food consumption patterns.

To receive abstract submission guidelines and/or further information, please contact the Conference on Dietary Assessment Methods, Harvard School of Public Health, 677 Huntington Ave, LL 23, Boston, MA 02115-6023; tel (617) 432-1171; fax (617) 432-1969.

Dietary Sources of Fats and Cholesterol in US Children Aged 2 through 5 Years

Frances E. Thompson, PhD, MPH, and Barbara A. Dennison, MD

ABSTRACT

Objectives. This study of lipid intakes among preschool children (1) analyzed the contributions of 38 food groups to fat, saturated fat, and cholesterol intakes; (2) estimated the effects of food substitutions on intakes; and (3) examined demographic differences in food group intake and food group sources of these lipids.

Methods. The sample consisted of 547 children, aged 2 to 5 years, from the US Department of Agriculture's 1985 and 1986 Continuing Surveys of Food Intakes by Individuals. Dietary information for 4 nonconsecutive days throughout a year was used. All foods were classified into groups and the lipids contributed from each group were computed.

Results. Over 80% of the children consumed more total fat, saturated fats, and cholesterol than is recommended. The major source of total fat and saturated fats was whole milk; the major sources of dietary cholesterol were eggs and whole milk. Children's food consumption patterns differed by region of the country and race/ethnicity, providing opportunities to refine nutrition education interventions and evaluations.

Conclusions. By substituting lower-fat foods for the major sources of saturated fats, significant reductions in preschool children's intakes of saturated fats, fat, and dietary cholesterol could be achieved. (*Am J Public Health.* 1994;84:799–806)

Introduction

Numerous private and governmental organizations have recommended that children over 2 years of age restrict dietary fats and cholesterol.[1–3] Recent recommendations issued by the National Cholesterol Education Program's Expert Panel on Blood Cholesterol Levels in Children and Adolescents call for limiting the intake of saturated fatty acids to less than 10% of total calories, total fat to no more than 30% of total calories, and dietary cholesterol to less than 300 mg/day for children aged 2 years and older.[4] The American Academy of Pediatrics Committee on Nutrition concurred with these recommendations in 1992.[5] The recommendations are consistent with the *Dietary Guidelines for Americans* issued by the US Department of Agriculture (USDA) and the US Department of Health and Human Services.[6]

The dietary patterns of specific regional populations of young children have been examined.[7–9] We use dietary data from nationwide samples of US preschool-aged children to (1) estimate for various demographic subgroups the prevalence with which dietary lipid recommendations are met; (2) describe major food group sources of dietary fat, saturated fatty acids, and cholesterol; (3) estimate the effects of food substitutions on lipid intakes; and (4) analyze differences in food group consumption by various demographic variables.

Methods

Study Design

Data from USDA's 1985 and 1986 Continuing Surveys of Food Intakes by Individuals core sample were used. The design of these surveys provided two multistage stratified area probability samples of women aged 19 through 50 years and their children aged 1 through 5 years that were representative of the 48 conterminous states. Stratification variables of the sampling design included geographical location, degree of urbanization, and socioeconomic characteristics.

Although the same area segments were sampled in both the 1985 and 1986 surveys, different housing units were selected for each survey. To ensure comparability of the two surveys, data collection and processing procedures used were identical.

Assessment of Dietary Intake

Respondents were asked to provide six nonconsecutive 1-day dietary recalls collected at approximately 2-month intervals over a 1-year period. Interviews were conducted from April 1985 through March 1986 and from April 1986 through March 1987. In eligible households, all women aged 19 through 50 years at the time of initial contact and their children aged 1 through 5 years were asked to participate. Participating households were scheduled for interviews on different days of the

At the time of the study, Frances E. Thompson was with the Division of Nutritional Sciences, Cornell University, Ithaca, NY. She is now with the Division of Cancer Prevention and Control, National Cancer Institute, Bethesda, Md. Barbara A. Dennison is with the Department of Pediatrics, College of Physicians and Surgeons of Columbia University, New York, NY, and the Research Institute and Department of Pediatrics, Mary Imogene Bassett Hospital, Cooperstown, NY.

Editor's Note. See related editorial by Nestle (p 713) in this issue.

week, including weekends. For subsequent contacts, interviewers attempted to reinterview within 10 days of 2 months' time from the date of the last interview, and on a different day of the week. Each participating woman provided dietary intake information for herself and her children. The first interview was conducted in person; subsequent interviews were conducted by telephone. Standard interviewing methods were used, including probing for forgotten foods,[10,11] and standard household measuring cups and spoons and a ruler were used to assist respondents in reporting portion sizes.

Study Sample

Although the design of the surveys called for collection of 6 nonconsecutive days of dietary information, fewer than half of the respondents interviewed initially provided 6 days of dietary information. Consequently, USDA constructed a sample of all respondents who had dietary data for at least 4 of the 6 days. For this sample, the first day of information was included for all respondents. For those who had 5 or 6 days of dietary information, USDA randomly selected 3 additional days to be used in the data set. Of those children with food intake data from the initial interview, 62% of the 1985 core sample and 68% of the 1986 core sample had at least 3 additional days of dietary information. The resultant data set from the combined 1985 and 1986 core samples included 649 children, each with 4 days of dietary information. The study procedures and nonresponse analysis are described in detail elsewhere.[10–12]

Because the current dietary recommendations do not pertain to children younger than 2 years, 1-year-old children were omitted from these analyses, leaving 547 children in the sample. When population weights were applied, the children were distributed similarly across 1-year age groups. About 81% were White, 10% Black, 6% Hispanic, and 3% other. Eighteen percent lived in the Northeast, 24% in the Midwest, 33% in the South, and 25% in the West. Twenty-eight percent had household incomes at or below 130% of the federal poverty level, 45% had incomes between 130% and 300% of the poverty level, and 27% had incomes above 300% of the poverty level. These characteristics were distributed similarly across sex.

Variable Definition

Individual food items were classified into 38 food groups on the basis of similar patterns of use, frequency of use, and nutrient composition. (A description of the food groups is available from Dr Thompson.) Foods eaten together and reported as one food item (e.g., a beef sandwich) were categorized into mixture food groups.

For each respondent, the total amount of each food group consumed (in grams) was determined. In addition, the amounts of each of the three lipids highlighted by the National Cholesterol Education Program's pediatric panel—dietary total fat, saturated fatty acids, and cholesterol—consumed from each food group were computed.

The contribution of each food group to the intake of each lipid was examined in two ways: as the population proportion and as the mean proportion. The population proportion was estimated as follows:

$$\text{Population Proportion} = \frac{\sum_{i=1}^{n} F_i}{\sum_{i=1}^{n} T_i},$$

where F_i = the amount of lipid contributed by a particular food group for the ith individual, T_i = the total amount of lipid from all foods from the ith individual, and n = the number of individuals in the population.

With cholesterol from eggs as an example, this measure represents the proportion of all cholesterol consumed by the population that comes from eggs. Because a true measure of usual intake is unobtainable, this is the closest approximation.[13] However, because it is measured for the whole population, there is no way to examine the variance for this proportion or to examine it in relation to other variables. Therefore, the mean proportion was estimated as follows:

$$\text{Mean Proportion} = \frac{\sum_{i=1}^{n} \frac{F_i}{T_i}}{n},$$

where the terms are defined as previously.

Again using cholesterol from eggs as an example, the mean proportion represents the average contribution of eggs to cholesterol per person. Because the proportion (F_i/T_i) is calculated for each person individually, a standard deviation can be determined and the variable can be examined in relation to other measures. The use of multiple days of data legitimizes this approach.[13]

Analysis

Weighting factors to adjust for household and individual nonresponse were incorporated in all analyses. Proportions and means were estimated with SAS software (SAS Institute Inc, Cary, NC); standard errors and statistical significance were estimated with SUDAAN software (Research Triangle Institute, Research Triangle Park, NC).

Multiple regression analysis was used to examine the independent effects of various demographic characteristics on food group consumption (in grams per day). Independent variables included region of residence, household income (percentage of poverty level, adjusted for family size and household composition), sex, age, and race/ethnicity. Weighted least squares means were estimated for various subgroups: the weighted REG procedure of SAS was used to derive estimates of regression coefficients and then the weighted means for each category of interest were computed. Regression coefficients for continuous variables and statistical significance for all variables in the model were estimated through the REGRESS procedure of SUDAAN.

Results

Macronutrient and overall energy intakes increase with age (Table 1), ranging from 1371 kcal at age 2 years to 1539 kcal at age 5 years. However, cholesterol intake, percentage of calories from total fat, and percentage of calories from saturated fatty acids are similar across age groups, averaging 232 mg/day, 35%, and 14%, respectively.

Nearly all children aged 2 through 5 years consume diets with more than the recommended amounts of total fat and saturated fatty acids (Table 2). Although 75% of children consume less than 300 mg/day of cholesterol, 81% consume diets with more than 100 mg of cholesterol per 1000 kcal, an alternative standard for lower-energy diets.[14] Black children and children from the lowest-income households have diets least consistent with dietary fat and cholesterol recommendations.

Food Group Sources of Dietary Lipids

Total fat. For the total population of children aged 2 through 5 years, the major food group source of total dietary fat is whole milk, which contributes an estimated 6.4 g/day of fat, 11.3% of the total amount of fat consumed (Table 3). Sweet

processed cheese; franks, sausages, lunch meats, and bacon; and mostly grain mixtures contribute 1.8, 1.7, and 1.7 g/day, respectively, of saturated fatty acids. Sixteen food groups account for 89.4% of the saturated fatty acids consumed by the population.

Dietary cholesterol. Almost a third (30.3%; 70 mg/day) of the total amount of cholesterol consumed by children aged 2 through 5 years comes from the egg food group (Table 3). The food groups whole milk, sweet grain products, and beef (reported separately) contribute an additional 26, 18, and 16 mg/day, respectively, of dietary cholesterol. Twelve food groups account for 84.4% of the dietary cholesterol consumed by the population.

Effects of Food Substitutions on Lipid Intakes

By targeting children's major dietary sources of saturated fatty acids, one can examine the effects of potential changes. Whole milk, natural and processed cheese, and low-fat milks (e.g., skim, 1%, or 2% milk) contribute 33% of the saturated fatty acids in these children's diets (Table 3). Substituting 1% milk for all the whole milk consumed (cup for cup), part-skim-milk cheese for all the whole-milk natural cheese consumed (ounce for ounce), and skim milk for all of the low-fat milks consumed (cup for cup) would decrease the population's intake of saturated fatty acids (from 22.5 to 16.7 g/day), total fat (from 56.9 to 47.3 g/day), and cholesterol (from 209 to 174 mg/day). The 5.8-g/day reduction in saturated fatty acid intake is more than 90% of the 6.3-g/day reduction needed to achieve an average saturated fatty acid intake of 16.2 g/day (10% of total calories). These substitutions also result in a 9.6-g/day reduction in total fat, more than the 8.2-g/day reduction needed to achieve a total fat intake of 48.7 g/day (30% of total calories). These substitutions of lower-fat foods for higher-fat foods would reduce total energy intake from 1462 to 1363 calories. To compensate for this deficit, the diets can be made isocaloric by increasing the intake of low-fat complex carbohydrate food groups (grains, vegetables, and fruits), consistent with federal dietary guidelines.[3,4,6]

The food groups (1) franks, sausages, lunch meats, and bacon and (2) mostly grain mixtures are also among the top five food group sources of dietary saturated fatty acids. Reduced-fat turkey hot dogs or lunch meats or lean cuts of beef, poultry, or fish could be substituted for regular hot dogs or lunch meats. Reduced-fat versions of many grain mixtures are also available. In home-prepared versions, the total or saturated fat content could be reduced by using less fats and oils, substituting mono- or polyunsaturated fat for saturated fat, and substituting lower-fat cheese for regular cheese.

The population-level data presented guide the design and evaluation of nutrition education efforts for populations. Recommendations for particular individuals must be tailored to individual tastes and constraints. Not all individuals will find a given substitution acceptable and not all will use it all the time. Moderate changes in the major sources of saturated fatty acids for children will result in significant favorable changes in dietary intake for most children. When the dietary fat intake of young children is reduced, extremes need to be avoided, as very-low-fat diets with inadequate calories and nutrients may result.[15]

Demographic Differences in Food Group Consumption

The effects of various demographic variables on the consumption of selected food groups, with the effects of the other variables in the model controlled, are

shown in Table 4. Overall, the number of significant effects is small relative to the number of tests performed. Race/ethnicity and region are associated with significant effects in more food groups than are the other variables examined.

For example, significantly less total milk (whole milk and low-fat milk groups combined) is consumed by Black children than by White and Hispanic children and in the South than in the Midwest or West. Of the total milk consumed, children in the South consume a greater proportion as whole milk (84%) than do children in the Northeast (76%), the Midwest (58%), or the West (61%). This proportion is higher in Black (82%) and Hispanic (75%) than in White children (51%). Compared with White and Hispanic children, Blacks consume significantly more franks, sausages, lunch meats, and bacon. The proportion of total milk consumed as whole milk is significantly higher for lower-income households than for higher-income households.

Demographic Differences in Food Group Sources of Lipids

For children in all racial/ethnic groups and in all regions, whole milk is the major food group source of saturated fatty

acids; eggs and whole milk are major food group sources of dietary cholesterol; and whole milk, franks and related meats, or both are the major food group sources of total fat. Differences in overall food group consumption affect which food groups are other major sources of total fat, saturated fatty acids, and dietary cholesterol for children living in different regions (Table 5) and for different racial/ethnic groups (Table 6). For example, whole milk is the major food group source of total fat for Hispanics and Whites, whereas franks and related meats constitute the major food group source for Blacks.

Discussion

Several limitations in the data used for these analyses should be noted. First, mothers may have been unaware of what foods were consumed when their children were cared for by others. Recent studies indicate that the consensus recall method, in which the child and both parents participate, may provide better intake estimates than a report from one parent alone.[16] Second, the nutrient composition database used in the 1985 and 1986 USDA surveys lacked specificity with regard to foods consumed by Hispanics.[17] Nutrient data were based on commercially prepared, Americanized versions of Mexican foods and thus did not reflect traditional preparation methods or differences in preparation methods among Hispanic subgroups.

The small number of children in certain subgroups (e.g., Blacks [n = 46] and Hispanics [n = 32]) precluded testing for important statistical interactions involving race/ethnicity. For example, Hispanics living in the South and West (most of whom come from Mexico) may have different diets than Hispanics living in the Northeast (most of whom come from Puerto Rico). In addition, many statistical tests were conducted for the demographic comparisons, increasing the chances of detecting random rather than real effects. Thus, these results are more appropriately viewed as descriptive and suggestive of the need for corroboration from other work. However, results from other studies are consistent with our work. For example, our finding that Hispanics drink substantially more whole milk than low-fat milk is consistent with findings from other studies.[8,9,18] Similarly, our finding that more Black than White children and more lower-income households than higher-income households had diets that failed to meet dietary lipid recommendations is consistent with analyses of the second National Health and Nutrition Examination Survey.[19,20]

Finally, substantial secular changes in food consumption may have occurred since 1985 and 1986. More lower-fat food products are now offered in the marketplace. Consumption of whole milk decreased and that of low-fat milk increased between 1985 and 1990.[21] The effects of these trends on the dietary patterns of children should be examined as newer data become available.

Although numerous programs and initiatives provide dietary guidance for school-aged children,[22–24] comprehensive dietary guidance provided for preschool-aged children is limited. Recommendations are available in the National Cholesterol Education Program report.[4] USDA and the Department of Health and Human Services provide qualitative dietary guidance to Child Nutrition Program cooperators, including day-care providers.[25] The Supplemental Food Program for Women, Infants, and Children (WIC), which provides food vouchers for eligible low-income infants and children to age 5, offers opportunities to support consumption of low-fat products, both in choice of acceptable foods for vouchers and in nutrition education for clients.

Our results showing the importance of dairy products, particularly whole milk, to lipid consumption highlight the need to promote low-fat dairy products comprehensively throughout all food and nutrition efforts aimed at children, from preschool through adolescence. Analyses of differences in food consumption patterns among different demographic subgroups indicate that certain relationships are strong for all examined subgroups. However, differences in food group consumption do occur, and these differences should be incorporated into the design of nutrition education programs. Baseline assessment of dietary sources of lipids at the regional level may lead to more effective interventions and valid program evaluations. □

Acknowledgments

This study was carried out through the support of the Human Nutrition Information Service, US Department of Agriculture, Cooperative Agreement 58-3198-6-34 and the New York State Department of Health, Bureau of Nutrition, Contract C001038. The research was conducted using the Cornell National Supercomputer Facility, a resource of the Cornell Theory Center, which is funded in part by the National Science Foundation, New York State, the IBM Corporation, and members of the Cornell Theory Center's Corporate Research Institute.

Overweight Schoolchildren in New York State: Prevalence and Characteristics

Wendy S. Wolfe, PhD, Cathy C. Campbell, PhD, Edward A. Frongillo, Jr, PhD, Jere D. Haas, PhD, and Thomas A. Melnik, DrPH

ABSTRACT

Objectives. Childhood overweight is an increasing public health concern. This study was undertaken to determine the prevalence of overweight in elementary school children in New York State and to identify characteristics associated with child fatness.

Methods. Weight, height, triceps skinfold, midarm circumference, and a 24-hour dietary recall were taken on 1797 second- and fifth-grade students from 51 randomly selected schools in New York State outside of New York City. Parents completed a brief questionnaire.

Results. In comparison with 1974 and 1980 national reference data, up to twice the expected percentages of children had values above the 85th, 90th, and 95th percentiles for body mass index, triceps skinfold, and arm fat area. Regression analyses suggested that children who tended to be fatter were members of low socioeconomic status, two-parent (but not single-parent) households; those with few or no siblings; those who ate school lunch; and those who skipped breakfast.

Conclusions. The findings suggest that overweight is a problem among many elementary school children in New York State and that sociodemographic characteristics may be useful for targeting preventive efforts. (*Am J Public Health.* 1994;84: 807–813)

Introduction

Childhood overweight is an increasing public health concern, affecting as many as 20% to 25% of children in the United States.[1–3] According to one analysis, the prevalence of overweight in 6- to 11-year-old children increased by 54% from the early 1960s to the late 1970s.[2]

Overweight children have an increased risk of adult obesity that increases with the age of the child and the severity of the overweight.[4] In longitudinal studies, 27% of overweight 1- to 5-year-olds, 41% to 43% of overweight 3- to 9-year-olds, and 80% to 86% of overweight 10- to 13-year-olds have remained overweight as adults.[5–7] Overweight children also have increased risk factors for heart disease and diabetes and increased emotional stress, orthopedic disorders, and respiratory disease.[8]

The present study was undertaken to determine the prevalence of overweight and underweight in elementary school children in New York State outside of New York City and to identify characteristics associated with child fatness.

Methods

Sample Selection and Representativeness

A two-stage sampling technique was used. First, schools were randomly selected within 21 strata: 7 geographical regions in New York State outside of New York City and 3 socioeconomic status (SES) levels within each of these regions (based on 1980 census data). Of the 110 schools contacted by letter, 51 (46%) volunteered to participate. Parent consent forms with brief questionnaires were given to second and fifth graders; 1797 (51%) agreed to participate and were surveyed. Ages ranged from 6 to 12 years; the mean age of second graders was 7.9 (SD = 0.5), and the mean age of fifth graders was 10.9 (SD = 0.5).

Comparison of the students surveyed with data on all children in New York State outside of New York City suggested that the sample was representative.[9] As in the population, the sample was predominantly White, 18% lived with a single parent, and just over half had mothers who were employed.

Nonparticipation of schools did not appear to relate to the prevalence of overweight. Reasons included small school size, factors related to the dental component of the study,[10] and a misperception that the survey was intended only for low-income children.

Within the 51 schools, only two samples differed significantly from their school population in the proportion of non-White students, and two others differed in the proportion of students eligible for free or reduced-price school lunches. Because this number of differences would be expected as a result of sampling error, no schools were omitted from the analysis.[11]

TABLE 1—Prevalence Estimates (%) of Overweight in the Study Sample and in the Northeast NHANES II Subsample

	New York State Outside New York City, 1987/88					Northeast United States 1976–1980 (NHANES II)	
	NHANES I			NHANES II			
Percentile	BMI	TSF	AFA	BMI	TSF	BMI	TSF
>85th	28	23	NA	23	19	25	24
>90th	NA	NA	19	17	14	20	15
>95th	13	13	12	10	8	8	8

Note. Variation depended on the reference data used for comparison (National Health and Nutrition Examination Survey [NHANES] I [1971–1974][20] or NHANES II [1976–1980][15]), the cutoff level (percentile) used to define overweight, and the indicator used to measure child fatness (body mass index [BMI], triceps skinfold [TSF], or arm fat area [AFA]).

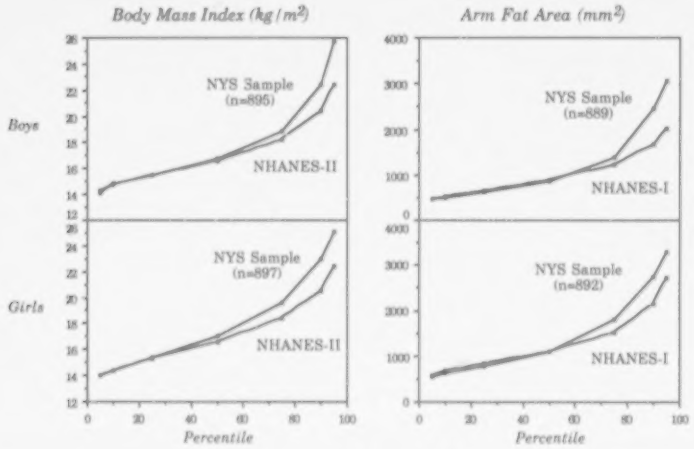

FIGURE 1—Sample arm fat area and body mass index cumulative distributions compared with the first and second National Health and Nutrition Examination Survey (NHANES I[14] and NHANES II[15]) national reference distributions, by sex.

Data Collection and Measurements

The best way to measure child fatness in the field is unclear. Various authors have recommended body mass index (weight/height^2),[12,13] triceps skinfold,[13] or arm fat area[14] (calculated from triceps skinfold and mid-upper-arm circumference: arm fat area [mm^2] = arm area [A] − arm muscle area [M], where $A = \pi/4 \times [C/\pi]^2$ and $M = [C - \pi T]^2/4\pi$ [C = arm circumference, T = triceps skinfold]) as the best indicator of body fat in school-aged children.

In this study, body mass index, triceps skinfold, and arm fat area were all used to measure child fatness. One of two trained examiners used standard procedures to measure weight, height, mid-upper-arm circumference, and triceps skinfold on each child. The principal examiner (first author) measured 1615 children between November 1987 and March 1988 and also administered a nonquantitative 24-hour dietary recall. The other examiner measured 182 children in the spring of 1987.

Measurement errors[16] for the four anthropometric indices were acceptable. Intraobserver (test–retest) reliabilities for each examiner ranged from 97% to 100%. Interobserver reliabilities, based on independent samples, were 93% to 100% between the principal examiner and an anthropometric expert and 96% to 100% between the principal and secondary examiners.

The best way to define overweight or underweight in children is also unclear. Therefore, various percentile cutoffs, as well as reference data from both the first and second National Health and Nutrition Examination Surveys (NHANES I and NHANES II), were used for comparison purposes in deriving prevalence estimates. In addition, because obesity rates are known to be higher in the Northeast than in other regions of the United States,[2,17] prevalence estimates for 6- to 12-year-olds in the Northeast subsample of NHANES II, with the total NHANES II distribution as the reference, also were calculated. Logistic regression was used to adjust the seasonality of this subsample to match that of the New York sample (November through March), since prevalence rates also vary with season.[2,17]

Five diet quality indices were derived from the recall: food diversity (number of different food items eaten), skipping of breakfast, consumption of no vegetable other than potatoes or tomato sauce, number of snack foods eaten, and a food group pattern score ("poor" defined as missing one or more of the four food groups or consuming two or more groups only one time each). Children who skipped breakfast were asked whether this was typical; most said it was.

On the basis of the parent questionnaire, children were classified as being of low SES if they met at least one of the following criteria: no parent working, eligibility for free or reduced-price school lunches, or receipt of social or food assistance. Children were classified as medium/high SES only if they met none of these criteria and had values for all three variables. Twenty-six percent of the children were considered low SES. In schools involved in the National School Lunch Program, children were classified as participants if their parent responded positively to the question "Does your child eat school lunch?"

Statistical Analysis

Regression models were developed to identify factors characterizing fatter from leaner children after adjustment for possible confounding and interactive effects. Factors examined were height, grade, age within grade, sex, race (White or African American), SES, family structure, school lunch participation, number of siblings, maternal employment, and the five dietary indices. ("Whites" included the small number of Hispanics and "others";

the body fatness of these groups did not differ significantly from that of Whites.) Because all variables were examined simultaneously for their effects after adjustment for the others, children with missing values for any of the variables, including those in nine schools that did not participate in the National School Lunch Program and those in six schools for which dietary data were not available, were omitted from the regression analyses.

Regression models were developed for each of six different anthropometric dependent variables. Two ordinary least squares models were developed for body mass index and arm fat area treated as continuous variables. Because their distributions were positively skewed and their variances increased with age and height, both were transformed into natural logarithms to make the regression residuals more symmetrically distributed.

To test for the risk of overweight or underweight, four additional models were examined with multiple logistic regression; body mass index and arm fat area were dichotomized into (a) overweight (>90th percentile) vs normal weight (≤90th and >10th percentile) and (b) underweight (≤10th percentile) vs normal weight. Body mass index values were compared with age- and sex-specific reference percentiles from the NHANES II national probability sample survey,[15] while arm fat area values were compared with reference percentiles developed by Frisancho from NHANES I.[14] Although derived from different surveys, these were the only published national reference percentiles available for body mass index and arm fat area when the regression analyses were done. For consistency in the analyses, the 90th percentile was selected as the cutoff for both indices (the 85th percentile was not available for arm fat area).

For the least squares analyses, a stepwise multiple regression procedure was run in which all main effects were retained and each conceptually plausible two-way interaction effect was tested; the least significant interaction was removed at each step, and those with a P value of .10 or less were retained.[18,19] This procedure was repeated retaining all significant two-way interactions and their inclusive main effects and testing the remaining main effects (retaining those with a P value of less than .05). The resulting models were then tested with logistic regression; variables were removed by means of a similar stepwise procedure.

TABLE 2—Sample Distributions of Physical Indices, Compared with Age- and Sex-Specific National Reference Percentiles

Indices and Percentiles	Boys (n = 900), %	Girls (n = 897), %	Second Graders (n = 960), %	Fifth Graders (n = 837), %	Total (n = 1797), %
Body mass index[a]

Results

Prevalence Estimates for Overweight and Underweight

The estimated prevalence of overweight in the sample (Table 1) varied with (a) the reference data used for comparison,[15,20] (b) the cutoff level used to define overweight, and (c) the indicator used to measure child fatness. Regardless, the prevalence was higher (by as much as twice) than that expected based on the US reference populations. Prevalence estimates differed little from those for the Northeast subsample of NHANES II, however.

The sample anthropometric distributions are shown in Figure 1 and Table 2.[14,15,21] A higher than expected percentage of children had values in the upper percentiles for body mass index, triceps skinfold, and arm fat area, while the percentage with values in the lower extremes (underweight) was similar to or less than expected. Weight status did not vary by grade or sex; within these categories, body mass index measurements were correlated significantly with both arm fat area (coefficients of .92 to .94) and triceps skinfold (.87 to .90).

Characteristics Associated with Child Fatness

In the least squares models (Table 3), arm fat area and body mass index were examined as unadjusted raw variables; therefore, most of the explained variation was attributable to biological variables (R^2s for the biological models alone were 25.4% and 11.4% for arm fat area and body mass index, respectively, compared with 28.5% and 12.2% for the full models). As expected, fatness increased significantly with grade (age) and height, girls had higher arm fat area indices than boys,[22] and African Americans had lower arm fat area indices than Whites.[23]

In the arm fat area model, all sociodemographic variables entered except maternal employment were related to child fatness after adjustment for the others. In the body mass index model, similar results were found, although some relationships were slightly less significant.

TABLE 3—Multiple Least Squares Regression Models of Child Fatness as a Continuous Variable

Explanatory Variable	Dependent Variable: Arm Fat Area (n = 1135) Regression Coefficient	SE	Dependent Variable: Body Mass Index (n = 1138) Regression Coefficient	SE
Biological variables				
Grade (5th vs 2nd)	.36*	.030	.10*	.010
Age within grade, m[a]	−.007*	.003	.003*	.001
Height within grade, cm[a]	.046*	.005	. . .[b]	. . .
Sex (female vs male)	.28*	.058	.034	.019
Race (African American vs White)	−.32*	.062	−.040	.021
Sociodemographic variables				
SES score (medium/high vs low)	−.094	.052	−.031	.018
Family structure (single parent vs dual parent)	−.15*	.062	−.046*	.021
School lunch (participants vs nonparticipants)	.12*	.037	.039*	.012
Siblings 1 (single child vs 1 or more siblings)	.10*	.046	.020	.015
Siblings 2 (3 or more siblings vs 2 or less)	−.084*	.042	−.027	.014
Breakfast skipping (no breakfast vs some breakfast)	.11*	.056	.063*	.019
Interactions				
SES × Family Structure	.22*	.084	.072*	.028
SES × Height	−.014*	.005	. . .	. . .
SES × Sex	−.10	.067	−.032	.022
Breakfast × Family Structure	−.26*	.12	−.14*	.038
Intercept	6.76*	.060	2.81*	.020

Note. SES = socioeconomic status.
[a]Centered around the mean for each grade.
[b]Not entered (already adjusted for in dependent variable).
*$P < .05$.

Low-SES children tended to be fatter (by about 5%) than medium/high-SES children, except in single-parent households (an interaction). The inverse relationship of fatness with SES was stronger in girls than in boys; although this interaction was slightly less significant than the $P < .10$ cutoff, it was kept in the model because of the similar findings in adults.

Children in single-parent families tended to be thinner than those in two-parent families. Children who participated in school lunch tended to be slightly but significantly fatter than those who did not; this relationship held even when children eligible for free or reduced-price lunches were omitted from the comparison. Children with no or few siblings tended to be fatter than those with many siblings. Finally, children who skipped breakfast tended to be fatter than those who ate breakfast, except in single-parent households. The other dietary indices examined did not relate to child fatness.

On the basis of the body mass index model, these relationships translate into low-SES children being from 0.4 to 1.8 kg (1 to 4 lb) heavier (depending on their other characteristics), single-parent children being up to 0.4 kg (1 lb) lighter, school lunch participants being 0.7 to 0.9 kg (1.5 to 2 lb) heavier, children with no siblings being 0.4 to 0.7 kg (1 to 1.5 lb) heavier, and children with three or more siblings being 0.4 to 0.7 kg (1 to 1.5 lb) lighter than their respective counterparts.

Characteristics Associated with Overweight and Underweight

On the basis of chi-square tests with no adjustment for other variables, there was significantly more overweight (> 90th percentile for body mass index or arm fat area) in children with few or no siblings, those with employed mothers, and those who ate school lunch. There was more underweight (≤ 10th percentile) in children with single parents.

The logistic regression models (Table 4) mostly supported the findings of the least squares models. African-American children were slightly less likely to be overweight, based on body mass index, and much more likely to be "underfat," based on arm fat area, than White children. In two-parent households, medium/high-SES children were about half as likely as low-SES children to be overweight and slightly less likely to be underweight. In single-parent households, on the other hand, SES was not significantly related to overweight or underweight, except for a trend toward medium/high-SES children being heavier than low-SES children.

Compared with children who did not eat school lunch, children who ate school lunch were about half as likely to be underweight and somewhat, but not significantly, more likely to be overweight. Children with no siblings were somewhat more likely, and those with three or more siblings significantly less likely, to be overweight than those with one or two siblings. In two-parent families, children who skipped breakfast were almost twice as likely as breakfast eaters to be overweight; they were less likely to be underweight, as measured by arm fat area, than those who ate breakfast.

Discussion

Because the exact degree of child fatness related to later health problems is unknown, there is no health-based definition of child overweight. Its diagnosis thus remains statistical rather than pathological, and the prevalence in a given population depends on the reference data, the cutoff level, and the indicator used.

The most useful reference data are those representative of the US population. Therefore, the sample measurements were compared with the national NHANES I and NHANES II survey data. Because children in the nation as a whole became fatter during the 1970s,[2] the prevalence of overweight in the sample is higher when compared with NHANES I national percentiles than with NHANES II percentiles, even though both data sets are representative samples of healthy individuals in the United States.

As far as cutoff level, values over the 95th percentile clearly represent a nutritional concern. Many also recommend use of the 85th percentile to define overweight in children, as is used increasingly in adults.[24–26] All three of the fatness indicators resulted in similar prevalences

TABLE 4—Odds Ratios (95% Confidence Intervals) of Being Overweight or Underweight Compared with Normal Weight, Based on Logistic Regression, for Each Explanatory Characteristic

Explanatory Characteristic	Dependent Variables: Overweight (>90th Percentile) Body Mass Index	Overweight (>90th Percentile) Arm Fat Area	Underweight (≤10th Percentile) Body Mass Index	Underweight (≤10th Percentile) Arm Fat Area
African American vs White	0.43[a] (0.19, 0.98)	0.87 (0.44, 1.73)	1.57 (0.72, 3.43)	3.63[a] (1.94, 6.80)
Medium/high vs low SES[b]				
In 2-parent families	0.53[a] (0.35, 0.80)	0.59[a] (0.40, 0.87)	0.57 (0.30, 1.08)	0.79 (0.42, 1.47)
In 1-parent families	2.01 (0.93, 4.36)	1.14 (0.53, 2.43)	0.76 (0.26, 2.25)	0.72 (0.28, 1.83)
Single-parent vs dual-parent family[b]				
In low-SES families	0.54 (0.27, 1.08)	0.62 (0.33, 1.16)	0.90 (0.38, 2.12)	1.28 (0.59, 2.81)
In medium/high-SES families	2.05[a] (1.12, 3.77)	1.20 (0.66, 2.18)	1.21 (0.48, 3.07)	1.17 (0.52, 2.63)
School lunch participants vs nonparticipants	1.48 (0.96, 2.27)	1.40 (0.95, 2.08)	0.66 (0.38, 1.14)	0.51[a] (0.32, 0.82)
Single child vs 1–2 siblings	1.46 (0.91, 2.34)	1.35 (0.88, 2.08)	1.51 (0.79, 2.88)	0.96 (0.50, 1.83)
3 or more siblings vs 1–2	0.60[a] (0.37, 0.98)	0.50[a] (0.31, 0.82)	0.66 (0.32, 1.37)	0.90 (0.50, 1.61)
No breakfast vs some[b]				
In 2-parent families	1.95[a] (1.17, 3.25)	1.51 (0.92, 2.46)	1.36 (0.59, 3.17)	0.23[a] (0.06, 0.97)
In 1-parent families	0.64 (0.20, 2.03)	0.43 (0.12, 1.54)	0.69 (0.15, 3.28)	0.61 (0.17, 2.22)

Note. The ratios for each explanatory characteristic have been adjusted for the other characteristics. SES = socioeconomic status.
[a]Significant based on 95% confidence interval not including odds ratio of 1.0.
[b]Significant interaction with following variable.

of overweight, although body mass index tended to give higher prevalences than triceps skinfold or arm fat area.

Regardless of the definition, the prevalence of overweight in the sample is substantially higher than that in the nation in 1974 or 1980. This is a concern because it may result in increased rates of adult obesity and rising health care costs, supporting the need for obesity prevention efforts starting in childhood. While the results probably reflect a greater current prevalence of child overweight in New York State than in the nation overall, similar to that found in the Northeast subsample of NHANES II, children nationally may well have increased in fatness between the most recent national survey and the present New York survey.

The prevalence of underweight in the study sample was similar to that in the nation in 1980, suggesting less of a problem than for overweight. However, this finding does not imply adequate dietary quality or the absence of at least episodic hunger (food insecurity) or that some children are not experiencing health problems due to being underweight.

The multivariate analyses identified several factors related to the degree of fatness in children. The lower arm fat area but not body mass index values of African Americans relative to Whites, similar to skinfold vs body weight findings from other studies,[22,26] may relate to racial differences in fat patterning rather than to differences in overall fatness.

The relationship between SES and child overweight is unclear in the literature. An inverse relationship like that revealed in this study was found in three other large US studies, including the National Health Examination Survey.[27–29] However, a positive relationship was found in the Ten State Nutrition Survey (except for an inverse relationship in late teen girls)[30] and the Tecumseh community study.[31] No relationship was found in three other large US studies.[32–34] In an extensive review of studies of all sizes in the United States and other developed countries, no clear trend emerged.[35] However, most of the relationships in girls were in the inverse direction, similar to the trend found in the present study and corresponding to differences found in adults.[35] This suggests that the trend toward females of lower SES being fatter may begin in childhood.

The interaction between SES and family structure, such that low-SES children tended to be fatter than higher SES children except in single-parent households, may be due to single-parent low-SES families being even poorer (in all necessary resources) than two-parent low-SES families. Although further study and better measures of SES are needed, this suggests a nonlinear relationship between SES and overweight, such that overweight is lowest in the very poor and in the wealthy and highest in the somewhat poor. Of four other studies that examined the relationship between child overweight and single parenthood, two showed a positive association[36,37] and two showed no association[38,39]; however, none controlled for SES.

A positive relationship between child fatness and participation in school lunch also was found in the national evaluation of the School Lunch Program.[40] The causal nature of this relationship is unclear, however. For example, children who choose not to eat school lunch could be leaner because they are pickier eaters or have more health-conscious parents. On the other hand, school lunches have been suggested to be high in fat,[41–43] which could lead to greater fatness in children.

The inverse relationship between the number of children in the family and child fatness has been found in a number of other studies,[36,44,45] but the mechanism remains unclear. Children with more siblings may be more physically active.

The positive association between breakfast skipping and overweight also was found in a study of adolescents,[46] but the pathway is unclear. Those who skip breakfast may eat more later in the day or be less active, or already-overweight children may tend to skip breakfast in an attempt to lose weight.

Maternal employment was not related to child overweight, as found elsewhere.[38,44] Other factors reported to relate to child overweight but not examined here include activity level and television viewing.[47]

In conclusion, the prevalence of overweight among school-aged children in New York State outside of New York City (14% to 28%, depending on the definition) is high in comparison with national reference data. Children who tended to be fatter were members of low-SES, two-parent households, those with few or no siblings, those who ate school lunch, and those who skipped breakfast. These variables may be useful for targeting interventions to prevent child overweight, although further research is needed to better understand the relationships and their mechanisms and to identify other related factors. □

Acknowledgments

Support for this work was provided by the Nutrition Surveillance Program of the New York State Department of Health and a National Institutes of Health nutrition training grant (DK07158).

We would like to thank Dr Jay Kumar and Annette Palk of the New York State Dental Bureau for sample selection and recruitment, Dr Tom Santner and Gail Rothe for help with data analysis, Janet Weber for the initial data collection, Dr Mary Fran Sowers and Deb Spicer for help in the initial design of the project, and Gayle Leitch Kelly for her administrative support.

5-A-DAY: Dietary Behavior and the Fruit and Vegetable Intake of Latino Children

Charles E. Basch, PhD, Patricia Zybert, PhD, and Steven Shea, MD

ABSTRACT

Objectives. The purpose of the study was to examine children's intake of fruits and vegetables in relation to the recent national "5-A-DAY" campaign.

Methods. Four 24-hour dietary recalls per child collected from 205 mothers of 4- to 5-year-old urban Latino children were used to analyze average 5-A-DAY fruit and vegetable consumption and examine associations between 5-A-DAY consumption, nutrient intakes, and eating patterns.

Results. The reported mean servings per day of fruits and vegetables, as defined by 5-A-DAY criteria, were 1.8 and 1.0, respectively, with only 6.8% (n = 14) of the children averaging five or more servings per day. Fruit juice accounted for 36% of 5-A-DAY servings. There were significant linear trends in intake of vitamins A and C, potassium, iron, cholesterol, protein, and fiber across quintiles of 5-A-DAY intake. There were no differences among quintiles in intake of saturated or total fat or in servings from most non–5-A-DAY food groups.

Conclusions. Latino children's intake of fruits and vegetables falls far short of current recommendations. Fruit juice accounted for a disproportionate amount of 5-A-DAY intake in this population. Sensible 5-A-DAY interventions should take into consideration the existing eating patterns of the target population. (*Am J Public Health.* 1994;84: 814–818)

Introduction

Systematic reviews of epidemiologic studies in adults indicate that higher levels of fruit and vegetable intake are associated with reduced risk of cancer at several sites.[1–8] As a result, as one of its cancer and nutrition risk reduction objectives for the year 2000, the US Public Health Service,[1] with wide support from other agencies,[9–13] has called for adults to increase servings of fruits and vegetables from an estimated current average of 2.8 servings per day to five or more servings per day. In accordance with this goal, the National Cancer Institute (NCI), with the cooperation of selected food industry representatives, has sponsored a multifaceted national campaign known as "5-A-DAY."[14] Although the 5-A-DAY recommendation was formulated with adults in mind, the Public Health Service has also recommended that children 2 years of age and older progress toward this dietary pattern.[1]

The weight of existing evidence supports protective health effects for a dietary pattern high in fruit and vegetable intake without identifying the specific vitamins, minerals, or nutrients responsible for these effects.[4,5,15] Causal mechanisms involved in the relationship between fruit and vegetable consumption and reduced cancer risk[4] may involve individual responses to dietary factors and nutrient interactions, which are themselves determined by genetic, physiologic, and life-style factors.[15] Thus, even though basic and epidemiologic research have identified specific vitamins, minerals, micronutrients, and macronutrients as the most likely agents responsible for the association between fruit and vegetable intake and cancer, the 5-A-DAY message is not to increase intake of these nutrients per se but to increase intake of fruits and vegetables. The emphasis on foods as opposed to nutrients[16] exemplified by the 5-A-DAY program reflects a relatively recent focus in public health nutrition.

While there has been some research describing fruit and vegetable consumption patterns and associated nutrient intakes in adults,[17,18] we did not identify any such studies in young children. Current eating behaviors of a target population should guide the formulation of effective, acceptable, and sustainable 5-A-DAY intervention strategies. We therefore analyzed repeated 24-hour dietary recalls in a sample of 205 urban Latino children to describe intake of 5-A-DAY foods, to determine whether high 5-A-DAY food consumption was associated with differential intake of specific nutrients and calories, and to examine whether high 5-A-DAY consumers substituted fruits and vegetables for other foods not in the 5-A-DAY group or added fruits and vegetables to a similar underlying diet.

Methods

Study Sample

Subjects were young healthy Latino children and their mothers (n = 214 mother/child pairs) who participated in a 3-year observational study of children's

diet and physical activity. All subjects were living in New York City. None of the children were on special diets. Recruitment was mainly from a large urban pediatric practice and has been described in greater detail elsewhere.[19] Analyses for the present study included all Latino mother/child pairs with four completed 24-hour dietary recalls for the child taken during the first year of the study (n = 205; 103 male children). At the time of the first recall, children's mean age was 4.4 years (SD = 0.34) and mothers' mean age was 31.8 years (SD = 5.2). Spanish was the language spoken at home by 95% (n = 195) of these families. More than 90% of the children for whom we had birthplace data (n = 184) were born in the United States. Seventy-four percent of the mothers were born in the Dominican Republic. Ninety percent of the mothers received Medicaid.

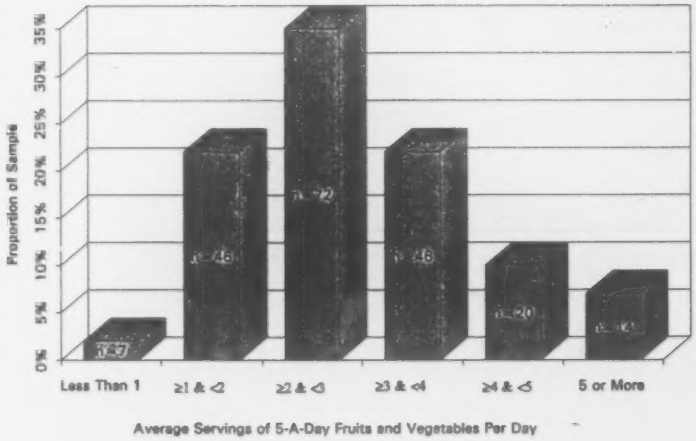

FIGURE 1—Frequency distribution for proportion of children (n = 205) who consumed varying serving levels of 5-A-DAY fruits and vegetables derived from an average of four dietary recalls over 1 year.

Measurements

From 1986 to 1989, trained research staff interviewed mothers (usually in Spanish) at our community-based field site. An existing reliable and validated protocol[20,21] was used to collect up to seven 24-hour dietary recalls over the course of 3 years. Additional descriptions of the data collection procedures and the nutrient analysis program and database have appeared in other published reports, and support for the reliability and validity of mothers' reports of children's diet has been shown.[20,21]

Typical nutrient intakes for each child were derived by averaging results from the four 24-hour recalls collected during the first year of the study. Inclusion/exclusion criteria and serving size guidelines specified by NCI[14] were used to calculate the number of servings of 5-A-DAY fruits and vegetables for each recall. Avocados, coconut, olives, nuts, and seeds were excluded, as were foods that were sweetened or fried. Only 100% nonsweetened fruit juices were included. Lacking complete information in our dietary recalls and nutrient database, we assumed that all apple juice consumed was unsweetened. Mixed vegetable dishes were included if the percentage of calories from fat was less than 30, the percentage of calories from saturated fat was less than 10, and the number of milligrams of sodium per serving was less than 360.[14] 5-A-DAY standard serving sizes are one piece of fresh fruit, one-half cup of cooked fruit and vegetables, six fluid ounces of juice, one cup of leafy vegetables, or one-fourth cup of dried fruit. In this paper, 5-A-DAY fruit and vegetable consumption represents the sum

across all reported eating occasions of 5-A-DAY eligible fruits and vegetables presented in terms of 5-A-DAY standard serving sizes.

5-A-DAY fruits were categorized as (1) fresh fruits, (2) fruit juices, or (3) others. 5-A-DAY vegetables were categorized as (1) beans and legumes; (2) dark green leafy, green nonleafy, or deep yellow vegetables; or (3) others.[14] This last vegetable group included homemade stews and soups meeting the NCI sodium and fat restrictions if one cup of the recipe provided at least one-half cup of vegetables.*

Statistical Analysis

Means and standard deviations for typical daily 5-A-DAY fruit and vegetable consumption were calculated. Children were then classified into quintiles of 5-A-DAY servings per day. Linear trends[22] across quintiles were tested for calories and selected nutrients and for numbers of servings from each food group. The regression technique recommended by Willett[23–25] was used to adjust nutrients to control for caloric intake. The natural logarithm transformation [ln $(x + 0.5)$] was used to normalize skewed distributions of both nutrient intakes and numbers of servings. Untransformed values are presented in the tables, but all statistical analyses involving significance testing and calorie adjustment of nutrients were performed on transformed data.

Results

The mean number of servings of 5-A-DAY fruits and vegetables consumed per day was 2.8 (SD = 1.3), and the median was 2.7 (Table 1). There was no significant difference in the proportion of boys and girls across the quintiles of 5-A-DAY intake ($\chi^2 = 2.7$, 4 *df*). There was substantial variability in consumption of fruits and vegetables across quintiles. In comparison with children in the lowest quintile, children in the highest quintile consumed more than three and a half times as many 5-A-DAY servings (4.8 vs 1.3) (Table 1). Only 14 of the 205 children in the study (6.8%) averaged the five or more servings a day recommended by the Public Health Service[1] (Figure 1).

About two thirds of the children (n = 128) consumed less than two servings of fruit per day. Only one child consumed three or more servings of vegetables per day. Children in all quintiles consumed more servings of fruit than of vegetables (mean = 1.8 vs 1.0 for the total sample) (paired $t = 10.7$, $df = 204$, $P < .001$). Fruit juice was the largest source of 5-A-DAY servings, accounting for 36% of total 5-A-DAY intake and 56% of 5-A-DAY fruit intake for the sample as a whole. Orange juice was by far the most popular fruit consumed in our sample. Dark green leafy, green nonleafy, and deep yellow vegetables were consumed least frequently (mean = 0.1, SD = 0.2, for the total sample).

The children who consumed more 5-A-DAY servings per day had slightly higher daily caloric intakes ($P < .01$), with a difference of approximately 14% (206 calories) between the lowest and highest quintiles of 5-A-DAY servings (Table 2). There were significant linear trends ($P < .001$) in intake of vitamins A and C, potassium, iron, cholesterol, protein and fiber, with intakes increasing from lowest to highest quintiles of 5-A-DAY intake. After calorie adjustment, the significance of the linear trends for cholesterol and protein dropped to $P < .01$. The others remained unchanged. There were no differences across quintiles in percentage of calories from saturated or total fat.

With regard to intake of non–5-A-DAY foods, children in the highest quintile of 5-A-DAY food intake ate more than twice as many eggs as those in the lowest quintile (0.7 vs 0.3 eggs per day), explaining their higher dietary cholesterol intake. Children in the highest 5-A-DAY quintile also consumed fewer servings of fruit punch and soda (0.3 vs 0.8 servings per day) and slightly more un-

*Appendixes ("Appendix A—Mean No. of 5-A-DAY Servings per Eating Occasion" and "Appendix B—Thirty-three Food Groups [US Dept of Agriculture Typology] Excluding 5-A-DAY Fruits and Vegetables") are available from the author.

fried poultry and fried fish. There were no other differences across the quintiles in numbers of servings from any of the non–5-A-DAY food groups analyzed.

Discussion

In our sample of 4- to 5-year-old urban Latino children, even those in the highest quintile of 5-A-DAY fruit and vegetable consumption averaged fewer than the five servings a day currently recommended by the Public Health Service.[1] Only about one third averaged two servings of fruit per day, and just one child averaged three servings of vegetables per day. Fruit juice, usually orange juice, was the most prevalent source of 5-A-DAY servings. Children in our sample averaged one serving of fruit juice per day but only one half of one serving of fresh fruit per day. They consumed almost no dark green leafy, green nonleafy, or deep yellow vegetables.

It is perhaps unreasonable to expect young children to eat the same number of adult-sized portions of fruits and vegetables as adults. In our sample, the standardized 5-A-DAY fruit serving sizes were compatible with children's actual consumption patterns, but the standardized 5-A-DAY vegetable serving sizes were generally too large (data not shown). Nevertheless, even if we halve vegetable serving sizes, thereby doubling the number of servings of vegetables, only children in the top quintile of 5-A-DAY consumption average five or more servings per day.

The direct associations between servings of fruits and vegetables and intakes of vitamins A and C, potassium, and dietary fiber were expected. Fruits and vegetables are rich sources of these vitamins and nutrients. There was no evidence that implementation of the 5-A-DAY dietary guideline would reduce children's percentage of calories from saturated or total fat.

On the basis of analyses of variance of the average number of servings from each of the non–5-A-DAY food groups by 5-A-DAY classification, the children in our sample who ate more 5-A-DAY servings generally did not substitute fruits and vegetables for other foods (data not shown). They added fruits and vegetables to an underlying diet that did not differ greatly across quintiles of 5-A-DAY intake. The one substitution we found was fruit juice for fruit punch and soda. Children in the highest quintile consumed 3.4 times as much fruit juice a day as children in the lowest quintile but less than half the amount of punch and soda. Examining individual recalls rather than averages for each child, we found that punch and fruit juice were essentially interchangeable. Days with low juice consumption were characterized by high punch consumption, and vice versa (data not shown). The only other statistically significant differences found were higher egg, unfried poultry, and fried fish consumption for high 5-A-DAY consumers.

Patterson et al. analyzed dietary recall data from the second National Health and Nutrition Examination Survey (NHANES II), which represents the adult civilian noninstitutionalized population of the United States in 1976 through 1980.[18] Few adults (9%) consumed three or more servings of vegetables and two or more servings of fruit a day. Vegetables were more commonly eaten than fruits, with mean servings per day of 1.8 and 1.1, respectively. Among the children we studied, fruits were more commonly eaten than vegetables. This reversal suggests the need for different emphases in 5-A-DAY campaigns directed at children and at adults.

In the NHANES II data, total fat intake increased with servings of fruits and vegetables, and the percentage of calories from total and saturated fat varied directly with servings of vegetables and inversely with servings of fruits. In our data, total fat intake did not rise with increased 5-A-DAY consumption. When analyzing the data to determine whether intake of fruits alone or vegetables alone was associated with intake of percentage of calories from saturated and total fats, we found no association between percentage of calories from fats and fruit intake and an inverse association between percentage of calories from fats and vegetable intake (data not shown). These differences are not surprising when methods are compared. We followed the recently formulated NCI 5-A-DAY inclusion/exclusion criteria and serving size definitions,[14] which the Patterson paper predates.[18] Particularly relevant is the fact that we excluded fried vegetables (e.g., french fried potatoes), while Patterson et al. did not. French fries were mentioned 80 times in our 820 recalls, and the average amount consumed per eating occasion was 13 strips. Furthermore, Patterson's "servings" are what we would call "mentions." They are not presented in terms of a fixed, predefined serving size for each food. In neither study was there a relationship between servings of fruits and vegetables and body mass index (data not shown).

Several limitations of our study warrant mention. First, the nutrient database we used, which was based on US Department of Agriculture Handbook 7[26,27] and supplemented by other sources,[28–31] did not always permit us to distinguish between allowed and disallowed fruits and vegetables, the most relevant instance being sweetened vs unsweetened apple juice. Nevertheless, we believe that our recall data adequately represent children's dietary intakes from both behavioral and nutrient perspectives.[19–21] Second, while our data collection plan was not designed to assess directly the effects of seasonal variation, we did check for nonrandomness in the distribution of season of dietary recall by quintile of 5-A-DAY consumption. There was no relationship between season of recall and 5-A-DAY quintile. Third, we attempted to estimate typical consumption using only four 24-hour recalls over a 1-year period. In this sample, the intraclass correlation for the number of 5-A-DAY servings was .55 (.46 for fruits and .57 for vegetables). Finally, our assessment of children's diet was based on mothers' reports. Reanalyzing previously published data on the validity of such reports from a subsample of 55 children in this same study,[21] we found significant overreporting in only one of the six 5-A-DAY fruit and vegetable categories, namely dark green and yellow vegetables, and no significant underreporting. In the data analyzed here, children's average intake of dark green and yellow vegetables was only 0.1 servings per day. These findings support the reliability and validity of the data set as used in the context of this paper.

Generalizability of our results to groups of children of different ages or other ethnic backgrounds may be limited. The Latino population is important from a public health perspective because it is a substantial and rapidly growing segment of the population[32] that, relative to non-Hispanic Whites, has been shown to purchase[33] and consume[34] fewer low-fat foods. Our population was of low income (90% received Medicaid), and there is evidence in adults that those with lower incomes generally eat fewer fruits and vegetables.[17] Also, language and cultural differences may result in this population being harder to reach with public health nutrition campaigns aimed at the general public.

Sensible 5-A-DAY interventions must take into consideration the existing eating patterns of the target population. Fruit juices—particularly apple juice—

make relatively small contributions per calorie to intakes of vitamins A and C and dietary fiber, nutrients frequently implicated in the protective effect of a diet high in fruits and vegetables. For example, a 6-oz serving of frozen orange juice contains approximately 83 calories, 143 IU of vitamin A, 73 mg of vitamin C, and 0.8 g of fiber. The same amount of apple juice contains approximately 87 calories, no vitamin A, less than 2 mg of vitamin C, and 0.5 g of fiber. This issue of empty calories is especially relevant in our population since 44% of the children in our sample were above the 85th percentile of national norms for body mass index for their age and sex.[35] On the basis of our study, we would advocate increased consumption of fresh fruit and dark green leafy and nonleafy and deep yellow vegetables among children in our sample of low-income urban Latinos as a means of implementing the 5-A-DAY objectives. We would not advocate increased consumption of juice (especially fruit juice with a high calorie-to-nutrient ratio) in our sample. In addition, the Committee on Nutrition of the American Academy of Pediatrics[36] has expressed concern about gastrointestinal problems (chronic diarrhea, abdominal pain and bloating) related to excessive intakes of sorbitol from certain juices. The challenge for public health nutrition interventions is to find a balance between retaining the simplicity of the 5-A-DAY message and designing an intervention appropriate for the target population. □

Family Networks: Predictors of Nursing Home Entry

Vicki A. Freedman, PhD, Lisa F. Berkman, PhD, Stephen R. Rapp, PhD, and Adrian M. Ostfeld, MD

A B S T R A C T

Despite the importance of kin in caring for older relatives, few studies have examined the relationship between the family network and the risk of nursing home placement. Data from a cohort of noninstitutionalized elderly persons living in New Haven in 1982 were used to predict nursing home admission through 1985. Logistic regression analyses show that older persons who have regular contact with kin have a lower risk of institutionalization. For men, the spouse is most important in reducing the risk of entry; for women, having regular contact with at least one family member—of any relation—reduces the risk of entry. (*Am J Public Health.* 1994;84:843–845)

Introduction

Each year, over 1 million elderly persons are admitted to nursing homes.[1] A number of prospective studies have examined measures related to nursing home admission.[2–15] The strongest and most consistent predictors of nursing home entry are functional status, mental status, and age. In addition, as first demonstrated by Townsend,[16] the absence of family ties appears to be associated with institutional residence. More recently, studies have documented that the living arrangements of an older person before entry,[4–6,11,12] the recent loss of a close tie,[4,6] and more general measures of social contact[14,15] predict nursing home admission.

Together these findings suggest that social networks—family members in particular—may be important in preventing the institutionalization of an older relative. Nevertheless, to date only limited measures of the social network have been considered in analyses of nursing home admission. In this study we explore the effects of both the composition and the size of the family network on the risk of institutionalization for elderly men and women.

Data and Methods

Data for this study are from the New Haven, Conn, site of the Established Populations for Epidemiologic Studies of the Elderly. The sampling design for the New Haven study has been described elsewhere.[17,18] Weighted estimates represent the population age 65 years and older in New Haven in 1982.

The New Haven cohort consisted of 2 812 noninstitutionalized men and women age 65 years and older in 1982. Respondents were interviewed annually from 1982 through 1991. Fewer than 1% of participants were lost to follow-up over the study period. Sample characteristics at baseline (1982) are presented in Table 1.

In this study, we used 3 years of follow-up data from 1982 to 1985, during which 354 participants experienced at least one nursing home episode. Respondents were asked annually about nursing home admissions. For each reported admission, the name of the nursing home and the approximate length of stay were recorded. Dates of entry and exit were then confirmed with named institutions.

Results

Table 2 presents the mean values for a series of family network variables, by gender. We included in our definition of family network children and other close relatives with whom the respondent had weekly or monthly face-to-face contact. Respondents identified close relatives in response to the question, "Apart from your children, how many other relatives do you have that you feel close to? (People you feel at ease with, can talk to about private matters, can call on for help?)" The spouse was also considered a

At the time of the study, Vicki A. Freedman, Lisa F. Berkman, and Adrian M. Ostfeld were with the Department of Epidemiology and Public Health, Yale University School of Medicine, New Haven, Conn. One or more nursing home admissions, 1982–1985	6.4	11.5
Cohort size (unweighted no.)	1 169	1 643

Note. Data are weighted. EPESE = Established Populations for Epidemiologic Studies of the Elderly.
[a]Housing is age and income restricted.
[b]Housing is age restricted.
[c]One point given for each activity for which respondent reported needed help: walking, bathing, grooming, dressing, eating, getting from bed to a chair, and using the toilet.
[d]One point given for each Pfeiffer mental status question respondent answered incorrectly.

TABLE 2—Family Network Composition and Size, New Haven EPESE, 1982

	% of Elderly with Regularly Contacted Network Member		Mean No. of Network Members[a]	
	Men	Women	Men	Women
Network member				
Spouse	64.4	27.4	...	...
Children	65.2	66.0	2.3	2.2
Close relatives	55.3	55.9	3.1	2.9
Total contact with any network	91.6	87.7	4.3	3.8
Cohort size (unweighted no.)	1169	1643	...	...

Note. The family network included the spouse, children, and/or close relatives other than children (including siblings) with whom the respondent had regular face-to-face contact. Data are weighted. EPESE = Established Populations for Epidemiologic Studies of the Elderly.
[a]Means for persons with specified type of network member.

TABLE 3—Adjusted Odds Ratios of Nursing Home Entry, by Family Network Composition and Size, New Haven EPESE, 1982 through 1985

Network Characteristics	Mean (n = 1136)		Women (n = 1603)	
	OR	95% CI	OR	95% CI
Composition				
No spouse/spouse	3.2	1.6, 6.3	2.1	0.9, 4.8
No children/children	1.1	0.4, 3.2	0.7	0.4, 1.4
No relatives/relatives	1.5	0.8, 2.9	0.9	0.6, 1.5
Size				
2 vs 3+	1.8	0.8, 4.3	1.4	0.7, 2.6
1 vs 2	1.2	0.5, 3.0	1.0	0.5, 2.1
0 vs 1	0.8	0.1, 6.4	2.9	1.5, 5.1

Note. The family network included the spouse, children, and/or close relatives other than children (including siblings) with whom the respondent had regular face-to-face contact. Odds ratios (ORs) are adjusted for age, race, housing strata, reported limitations in activities of daily living, and cognitive performance. Data are weighted. CI = confidence interval; EPESE = Established Populations for Epidemiologic Studies of the Elderly.

member of the family network if he or she was reported as a member of the household in 1982.

In 1982, 91.6% of older men and 87.7% of older women in New Haven had regular contact with at least one family member (i.e., spouse, child, or other close relative including siblings). For persons with a family network, the mean family size was 4.3 and 3.8 persons for men and women, respectively. Although overall differences between older men and women are slight with respect to their family networks, the differential in the proportion of men and women with a living spouse is noteworthy.

Results from logistic regression models are presented in Table 3 for men and women. Effects of both the composition and size of the family network on the risk of nursing home entry are examined. The outcome of interest is whether or not a respondent had at least one nursing home admission during the study period. Models control for age, race, housing strata, limitations in activities of daily living, and cognitive performance. Confidence intervals (CIs) for relative risks are based on standard errors adjusted to reflect the sampling design of the study.

For men, the absence of regular contact with a spouse was highly associated with nursing home entry (odds ratio = 3.2, 95% CI = 1.6, 6.3). At the same time, none of the variables indicating the size of the network predicted nursing home entry. Thus, no matter how large the network of relatives, the spouse was most important in reducing the risk of nursing home entry for men.

In contrast, for women, the composition of the network was not particularly important, but the size of the network was predictive of admission. Specifically, the relative risk of entry for elderly women who had no contact with relatives compared with those who had contact with only one relative was 2.9 (95% CI = 1.5, 5.1). This finding suggests that having at least one regularly contacted family member, regardless of his or her relation, reduces the risk of entry for women.

Discussion

In this study, we used prospective community-based data on the elderly population of New Haven to examine the relationship between family networks and the risk of nursing home entry. Our analyses support the hypothesis that, for older persons, the presence of a family network is associated with a reduced risk of nursing home entry, even after controlling for important confounders.

In addition, findings suggest the roles of kin in preventing institutionalization may be distinct for older men and women. For men, network members do not appear to be interchangeable. No matter how large the family, the absence of a spouse nearly triples the risk of nursing home entry, with age, race, functional disability, and mental status controlled. In contrast, the risk of nursing home entry for women appears to be reduced in the presence of at least one family member, regardless of the type of relation.

A major strength of this analysis is that we used a random sample of community-dwelling elderly persons, followed prospectively over time. In addition, we had rich detail on the social network and functional ability of the cohort of elderly persons. This detail enabled us to explore the role of extended family members in nursing home entry.

Nevertheless, our analysis is limited in several ways. We were unable to examine characteristics of network members (i.e., sex, marital status), nor could we identify the relationship of relatives (other than children) to respondents. We also did not take into consideration possible changes in the network over time due to mortality. Further, sample size constraints prohibited any distinction between recuperative and custodial stays.

Despite these limitations, this study points to the importance of regular contact with family members in reducing the risk of nursing home entry for older persons. Health professionals interested in targeting programs to persons at high risk of institutionalization should consider not only functional and mental performance of older persons, but also the extent to which the family is able and willing to provide support in the community. Widowed, divorced, and never-married men are at particularly high risk, as are women without at least one regularly contacted family member. □

The Teaching of Occupational Health in US Medical Schools: Little Improvement in 9 Years

Jay M. Burstein, MD, MPH, and Barry S. Levy, MD, MPH

ABSTRACT

A questionnaire survey of the 127 US medical schools was undertaken to assess the present status of occupational health teaching as a follow-up to two prior similar studies. The present study revealed that 78 (68%) of the 115 responding schools specifically taught occupational health during the 1991/92 academic year, in comparison with 50% in the 1977/78 and 66% in the 1982/83 academic years. The median required curriculum time was 6 hours in 1991/92, as compared with 4 hours in both previous surveys. Despite the increasing recognition of occupational health and growth of information in this field of medicine, occupational health teaching to medical students has not progressed proportionately. (*Am J Public Health.* 1994;84:846–849)

Introduction

Occupational illnesses and injuries are significant problems in the United States. In 1990, there were an estimated 6.4 million work-related injuries and 332 000 new cases of occupational illness.[1] According to the National Safety Council, there were 10 500 work-related fatalities in 1990 alone.[2] These figures are considered gross underestimates of the actual numbers of occupational illnesses and injuries,[3,4] which are widespread and affect virtually all organ systems.[5]

However, the health care system in the United States is not able to meet the challenges of occupationally related and environmentally related illness and injury.[6] A significant contributing factor to this deficiency is the shortage of qualified occupational and environmental health physicians.[7] As of 1990, there was an estimated shortage of 3100 to 5500 physicians in occupational and environmental medicine.[8]

Occupational health is generally defined as the recognition, treatment, and prevention of work-related illnesses and injuries, and occupational medicine is typically defined as occupational health in a clinical context. There are several definitions of environmental health and environmental medicine. Environmental health is often defined as the recognition, treatment, and prevention of illnesses and injuries related to the environment, and environmental medicine is usually defined as environmental health in a clinical context. Some physicians consider occupational health as a subset of environmental health, and others consider these fields as distinct entities.

In recent years, there have been efforts to extend occupational medicine to include environmental medicine. For example, the American College of Occupational and Environmental Medicine and the Association of Occupational and Environmental Clinics are two organizations that focus on both occupational and environmental medicine. In this survey, we solicited responses about the teaching of occupational health and occupational medicine—and, to a limited extent, environmental health and environmental medicine—without defining these terms.

There has, however, been increased interest in occupational and environmental health. The Institute of Medicine has convened several committees to increase the dissemination of information and teaching of occupational medicine to medical students, residents, and physicians.[3,8,9] Several federally funded programs have been initiated to increase and expand occupational teaching and expertise. And the Agency for Toxic Substances and Disease Registry has supported the development of training materials and research fellowships in environmental medicine.[10]

Questionnaire surveys on the teaching of occupational health in US medical schools were performed during the 1977/78 and 1982/83 academic years.[11,12] These prior surveys revealed that occupational health was specifically taught to medical students in only 50% (1977/78) and 66% (1982/83) of medical schools. Occupational health was part of the required core curriculum in 30% (1977/78) and 54% (1982/83) of the schools. The required median time devoted to occupational health was only 4 hours in both surveys.

Physicians can make a considerable impact on the recognition, treatment, and prevention of work-related illness and injury if they are properly trained as students.[6,13–15] The present survey was undertaken to assess how much progress, if any, has been made in recent years in

teaching occupational health to medical students and to identify future needs and directions.

Methods

In September 1991, a questionnaire on the teaching of occupational health during the 1991/92 academic year was sent to all 127 US medical schools. The questionnaire, endorsed by the Association of Teachers of Preventive Medicine, was sent to chairs of departments of preventive and/or community medicine. For the 35 schools without a preventive and/or community medicine department, the questionnaire was sent to chairs of family medicine or, if there was no such department, internal medicine. A cover letter accompanied the survey, requesting that it be forwarded to the person most responsible for teaching occupational health to medical students. Two additional mailings and a telephone call were made to nonrespondents.

The survey elicited the same information as the two earlier surveys, as well as some additional information: name, title, and department of the person who coordinates the teaching of occupational health; the number of faculty members teaching occupational health; whether occupational health was specifically taught in 1991/1992; curriculum content and format; the number of years occupational health has been taught; curriculum requirements, including time devoted to occupational health; elective courses in occupational and/or environmental medicine; and any planned changes for the 1992/93 academic year.

Results

One hundred fifteen (91%) of the 127 medical schools in the United States responded to the survey. Occupational health was specifically taught to medical students in 78 (68%) of responding schools and was a required course or part of a required course in 69 (60%) schools. The median curriculum time devoted to occupational health was 6 hours (mean = 6.7) (Table 1), and occupational health had been specifically taught in these schools for a median of 8 years.

The following results apply only to the 78 schools specifically teaching occupational health, unless otherwise noted.

Coordinator/Director

Information regarding the title and professional qualifications of the coordinator/director of occupational health teaching was surveyed. A professor directed occupational health teaching at 26% of the schools; an associate professor, at 26%; an assistant professor, at 19%; and a "director," at 19%. Other responses included "chief" (3 schools), "head" (1 school), and "senior lecturer" (1 school). The coordinator/director was from a department of family/preventive/community medicine at most schools (65%). Other departments included internal medicine (17%), occupational/environmental health (10%), and epidemiology/public health (8%). At 54 (69%) schools, the coordinator/director was formally trained in occupational health. At 43 (55%) of these 54 schools, the coordinator/director was board certified in occupational health. The median number of faculty members involved in at least some teaching of occupational health was four.

Content of Courses or Clerkships

Almost all schools (95%) that specifically taught occupational health included specific information on particular work-related diseases such as occupational musculoskeletal disorders and occupational respiratory disorders in courses or clerkships (Table 2). Of the 78 schools specifically teaching occupational health, 28 (36%) offered visits to factories, clinical laboratories, or other work sites. Of these 28, 10 required written reports of visits by students. During visits, students spoke to health care professionals (17 schools), employers/managers (14 schools), workers (12 schools), and safety or industrial hygiene professionals (20 schools). Occupational health/medicine was integrated into the clinical curriculum in 39 (50%) of the 78 schools, usually during the family practice clerkship and

occasionally during the internal medicine clerkship.

Elective Curriculum

Sixty-one (78%) of the 78 schools specifically teaching occupational health offered elective courses and/or clerkships in occupational health or occupational medicine. Eight of these 61 schools had no required curricular time offered. Most of the electives were offered in the clinical years. Several were a combination of clinical and research experiences. Several schools offered occupational health as an elective segment of the required family or community clerkship. Other electives included nuclear health hazards, seminars in epidemiology and public health, agricultural medicine, and opportunities in occupational epidemiology. Elective courses in environmental health or environmental medicine were offered in 42 (54%) of the schools. Most of these electives were "environmental health" courses, but several schools combined environmental health with occupational health in an elective course or clerkship.

Research and Summer Experiences for Students

Forty-five (58%) of the 78 schools offered research projects or summer experiences. The median number of students participating in these projects was one (mean = 2.0).

Graduate and Continuing Medical Education

Faculty at 45 (58%) of the 78 schools specifically taught occupational health or occupational medicine to interns or residents. Continuing medical education programs were offered by 43 (55%) of these medical schools, usually as an annual occupational health update course, a seminar, or grand rounds.

Other Aspects

Library services for occupational health were, on average, rated between "fair and good." Occupational health teaching resources and teaching aids were, on average, rated "fair" by the respondents.

Sixty (77%) responding schools operated or were affiliated with an occupational medicine clinic.

Thirty-eight (49%) of the 78 schools specifically teaching occupational health and 8 (22%) of the 37 schools not specifically teaching occupational health planned changes in the 1992/93 academic year, primarily to expand programs.

Discussion

In the past 9 years, there has been almost no change in the percentage of schools specifically teaching occupational health to medical students, although there has been a minor increase in schools requiring occupational health as part of the curriculum (Table 1). In addition, there has been an increase of 2 hours to bring the median number of hours of required occupational health teaching to medical students to 6. These findings are discouraging, given the 9 years since the last survey.

A number of reasons might explain the minimal increases in occupational health education in medical schools during this period. Two possible factors are the lack of increase in faculty qualified to teach occupational health and the paucity of occupational health taught in courses other than preventive medicine and family practice.

The median number of faculty members per school who are teaching occupational health has remained unchanged since 1977/78. More occupational health faculty would probably lead to more occupational health in medical school curricula. Nevertheless, the survey revealed that occupational health was minimally represented in "traditional" medical school courses such as physiology, physical diagnosis, and pathology (Table 3). Only four schools taught occupational health during a physical diagnosis course, an important avenue for introducing occupational and environmental history-taking skills. Occupational health was taught during physiology and toxicology courses at only three schools. Realizing that the present number of faculty teaching occupational health has remained small and that occupational health teaching has a minor presence in the basic science curriculum, we were not surprised by these results.

Improvements can be made if schools exert a sincere commitment to occupational health teaching through empowering existing faculty in this field and providing more opportunities for teaching occupational health. This could occur through a greater number of lectures by faculty currently teaching occupational health. Furthermore, faculty teaching occupational health could educate other existing faculty not currently qualified to teach this subject. However, it will be difficult to substantially recruit future faculty qualified to teach occupational health without necessary funding. Since occupational medicine is not able to generate the same level of income as hospital-based specialties, such as surgery and internal medicine, it is vital that the federal government contribute to recruitment and faculty development in this field. In addition, funding for research activities in occupational health should be increased. Through increasing research activity, more academic occupational health physicians may be recruited, which may, in turn, provide greater opportunity for occupational health faculty to increase teaching within medical schools.

Other potential avenues exist for increasing the occupational health curriculum in medical schools. This could be accomplished through incorporating more occupational health information into the standard preclinical and clinical curricula. For example, information on occupational lung disorders can be taught during pathology or pulmonary medicine courses; occupational musculoskeletal disorders can be taught as a component of rheumatology and orthopedic surgery; toxicology concerning work-related exposures can be incorporated into pharmacology and/or toxicology courses; occupational history taking can be included as a component of physical diagnosis or a patient interviewing course; and occupational reproductive disorders can be taught in endocrinology or obstetrics and gynecology. During

these lectures, handouts and/or case studies could be used. In addition, occupational medicine could become a requirement during a mandatory family or community medicine rotation, as is the case in the curricula of 25 existing medical schools. This concept—incorporation of occupational health teaching into existing curricula—was recommended on several survey questionnaires that we received in response to questions on proposed changes in the teaching of occupational health.

In addition, work-site visits, summer experiences, and research activities provide excellent opportunities for occupational health education. However, in comparison with 1982/83, the present survey revealed a minor decrease in available research projects or summer experiences and a significant decrease in work-site visits. These activities potentially provide an experimental introduction to students unfamiliar with occupational/environmental health and an opportunity for interested students to further develop their knowledge and skills in this field. In addition to summer or research activities at the medical school, opportunities that already exist with the National Institute for Occupational Safety and Health or public health departments may also be made available to interested medical students.

The survey findings also suggest that there is room for improvement in both occupational health teaching resources and aids as well as in occupational health library services. Many of these educational tools are readily obtainable and will be especially helpful for schools that lack faculty with occupational and environmental medicine expertise. Case studies and teaching materials on occupational medicine could be circulated during classroom sessions. In addition, informal journal clubs, discussion groups, or seminars could be established for medical students. This may stimulate the interest of medical students and the commitment of faculty members. Furthermore, occupational health teaching could be included in continuing medical education programs, including grand rounds and didactic lectures in emergency medicine, internal medicine, and family practice departments.

As noted in the results, approximately one half of medical schools are currently teaching environmental medicine. Occupational and environmental medicine educators have recently expressed the need for occupational physicians to evaluate and treat environmental illness, because there are currently no specialists trained in this area of medicine.[16] As more experience in teaching this newly defined area is gained, we encourage the sharing of information among educators.

As more information on occupationally related and environmentally related illness and injury is collected and shared, the need for improving the recognition, treatment, and prevention of occupational illness continues to be evident. This can be better achieved through proper training and the development of needed skills. However, as evidenced by the survey, occupational health teaching in US medical schools continues to be minimal. Recent efforts to expand occupational and environmental health education in medical schools, such as those of the Institute of Medicine and other agencies, may soon reap benefits. Occupational health education in United States medical schools continues to be neglected. A greater commitment is needed to this important subject. □

International Infant Mortality Rates: Bias from Reporting Differences

Embry M. Howell, PhD, and Béatrice Blondel, PhD

ABSTRACT

International infant mortality statistics have caused concern in the United States, since the US ranking relative to other developed countries has declined since World War II. This paper suggests that there may be international differences in reporting of very-low-birthweight infants and perinatal deaths and that such reporting differences bias comparisons of national perinatal and infant mortality rates. Efforts must be made to adopt standard conventions for the inclusion of small, early infants and fetal deaths in rate calculations. (*Am J Public Health.* 1994;84:850–852)

Introduction

Because of their ready availability and recognized importance as health and social indicators, infant mortality rates are routinely used for comparing countries. These statistics have become a source of concern in the United States, because it appears that the degree of decline in US rates has been lower than in other developed countries since World War II.[1]

The usefulness of crude infant mortality rates in international comparisons is questionable because of differences in the registration of births and deaths among very-low-birthweight (<1500 g) infants. In most European Community countries, registration is limited to births and fetal deaths above 27 weeks of gestation.[2] In Norway, registration is at 16 weeks and above,[3] and, in other places such as Osaka Province, Japan, and parts of the United States, all products of conception may be registered even though such registration is certainly incomplete for early fetal deaths. Common practices may also vary at local levels.[4–7] These differences in laws and customs regarding registering fetal deaths and live births have an impact on reported mortality rates.[8,9]

Methods

The purpose of this paper is to present data on birthweight distributions for births and fetal deaths from a wide range of countries and to show how registration and reporting bias may affect mortality rates. We used national samples of births in the United States (1980) and France (1981); Michigan state vital statistics (1984); a birth registry from Lorraine, France (1984); and vital statistics from several countries or regions that were included in the International Collaborative Effort on Infant Mortality sponsored by the US National Center for Health Statistics.[10] The International Collaborative Effort countries and regions were England and Wales; Hungary; Osaka Province, Japan; Norway; Sweden; and several states in the United States: California, Georgia, Michigan, Minnesota, Missouri, North Carolina, Utah, and Wisconsin. To analyze underreporting of very small infants and the possible misclassification of fetal deaths, we also developed hypothetical data to illustrate how reporting may bias international comparisons of infant mortality rates.

Results

Table 1 provides sample survey data, vital statistics, and birth registry data from France and the United States. While French infants were smaller, on average, there were fewer reported very-low-birthweight births proportionately in France. Because mortality rates are extremely high in the very-low-birthweight category (more than 400 per 1000), any underreporting in this category will bias mortality rates. Table 1 also shows that, among fetal and neonatal deaths, the proportion of fetal deaths was substantially higher in Lorraine than in Michigan.

Other data show that in 1985 the United States, Norway, and Osaka Province, Japan, reported between 0.2% and 0.4% of births and fetal deaths as less than 500 g (top panel of Table 2). The proportion of very-low-birthweight infants and fetal deaths ranged from 0.7% in Sweden to 1.5% in Osaka, Japan. Many of these differences are due to differences in reporting requirements for fetal deaths. After excluding all fetal deaths under 28 weeks' gestation (bottom panel of Table 2), we found similar very-low-birthweight rates in Osaka, Norway, and Sweden, while the rates shown before exclusions are quite different.

The proportion of perinatal deaths reported as fetal deaths ranged from 33% in Hungary to 68% in France (Table 3), suggesting large differences across countries in categorizing live births and fetal deaths. These classification differences could bias international infant mortality rate comparisons, since fetal deaths are

Source. Data are from International Collaborative Effort on Perinatal and Infant Mortality.[10]

not included in routinely reported infant mortality rates.

Hypothetical data show how underreporting could bias perinatal mortality rates. In a hypothetical country, the actual very-low-birthweight proportion is 1.0%, but the reported percentage is only 0.5. Assume a very-low-birthweight perinatal mortality rate of 470 per 1000 and 100 000 reported live births and fetal deaths. There are actually 470 very-low-birthweight perinatal deaths, but only 235 are reported. The reported perinatal mortality rate is 15 per 1000, but correcting for underreported deaths would raise this rate substantially to 17.3 per 1000.

Another hypothetical example illustrates the impact of differences in the classification of fetal deaths. Two hypothetical countries each have 55 000 live births and fetal deaths, 1000 perinatal deaths, and identical perinatal mortality rates of 18.2 per 1000. However, in the first country 40% of perinatal deaths are classified as fetal deaths, while the proportion is 60% in the second country. Assuming identical postperinatal mortality, the infant mortality rates are very different in the two countries: 14.0 per 1000 in the first country and only 10.4 per 1000 in the second country. This is entirely due to differences in the proportion of fetal deaths among perinatal deaths.

TABLE 3—Proportion of Fetal Deaths among Perinatal Deaths: Selected Countries, 1985

Country	Fetal Deaths, %
England and Wales	56
France	68
Hungary	33

United States	43

Note. Fetal deaths of 28 weeks' gestation or more and infant deaths in the first 7 days of life are included.
Source. Data are from the International Collaborative Effort on Perinatal and Infant Mortality.[10]

Discussion

Differences in the completeness of reporting of low-birthweight births or fetal deaths and the classification of fetal deaths may substantially bias international comparisons. Such bias was suggested by Lee et al.[11] when they found that the poor ranking of the United States was mainly explained by a high rate of very-low-birthweight babies.

Numerous researchers have stressed the effects of variations in registration limits and the importance of standard rules for international comparisons.[12,13] The World Health Organization recommends that national statistics include all fetuses and infants weighing at least 500 g. In all countries, such recommendations should be used and guidelines developed for health care professionals emphasizing the importance of complete and accurate reporting of vital events. Until reporting becomes more uniform across countries, it is desirable to exclude the smallest birthweight births and to combine infant and fetal deaths before making international comparisons. □

Urinary Biological Monitoring Markers of Anticancer Drug Exposure in Oncology Nurses

Mary Anne Newman, PhD, MS, Barbara G. Valanis, DrPH, Rita S. Schoeny, PhD, and Shane Que Hee, PhD

ABSTRACT

People handling anticancer drugs or their wastes may absorb these potent genotoxic agents. The aim of this study was to determine the utility of some general urinary markers among 24 female oncology nurses handling these drugs in comparison with 25 "unexposed" nurses. The markers were the *Salmonella typhimurium* reverse and forward mutation assays, total thioethers, and D-glucaric acid. The reverse mutation assay was the most specific and sensitive marker for anti-cancer drug exposure. Use of the marker battery was no great advantage as a screening tool relative to use of the reverse mutation assay alone. Better recording of work practices in nurse work logs would have improved interpretation of results. (*Am J Public Health.* 1994;84:852–855)

Introduction

Anticancer drugs target cancers because cell division is rapid.[1–3] These drugs affect other proliferating noncancerous tissues (bone marrow, hair follicles, gastrointestinal–nasopharyngeal and genitourinary tract epithelia, and developing embryos).[1–5] Many antineoplastic drugs are carcinogens and teratogens.[4] Adverse effects include irregular menstrual period, testicular function suppression, hair loss, chromosomal abnormalities, decreased white blood cells, liver damage, and spontaneous abortion, as well as light headedness, dizziness, nausea, headache, cough, and skin/mucous membrane and allergic reactions.[1–5] Settings where many of these drugs are administered or prepared (hospitals, home health agencies, pharmacies, waste handlers, and outpatient settings) need sensitive, selective, noninvasive, and inexpensive screening tests reflecting absorption of many anticancer drugs.

Four noninvasive, general urinary antineoplastic drug markers were assessed relative to oncology nurse work practices as part of ongoing research programs.[6–14] The markers were *Salmonella typhimurium* reverse and forward mutagenicity, total thioethers, and D-glucaric acid. All increased for patients receiving high treatment doses.[11] The reverse mutation assay is the "gold standard" for detecting urinary point and frameshift mutagens.[15] About 60% of oncology nurse investigations[1–4,7–10,15–26] are positive. The forward mutation assay detects DNA large base deletions and insertions, base-pair changes, and frameshifts.[27] Thioethers reflect the glutathione detoxification of electrophiles, putative mutagens.[15,28] D-glucaric acid reflects microsomal mixed function oxidation in the liver and kidney and bladder β-glucuronidase activity.[15,29]

Materials and Methods

Populations and Sampling

Twenty-four "exposed" female oncology nurses and 24 "unexposed" female control nurses were selected from a larger study of health effects[7] associated with antineoplastic drug handling. A physical examination and questionnaires (demographic, general health, smoking, medication use, and perceived exposure data) were administered, and the nurses maintained work logs (frequency, extent, sources, and settings of exposure data).[7] Work practices were observed directly.

Spot (untimed) urine samples were collected in 1983 during physical examinations. The pH-adjusted and filtered urines[12] were frozen at −20°C.

Urinary Markers

Analysis occurred in 1985. Creatinine was measured by Du Pont Automatic Analyser[11] to account for dilution. Thioether and D-glucaric acid concentrations were determined with our optimized methodology.[11] Reverse mutations were measured with *S. typhimurium* strains TA1535 (point mutations) and TA98 (frameshift mutations)[11,12]; forward mutations were quantified with *S. typhimurium* strain TM677 clone 09.[11,12] Assays were with (+) and without (−) rat liver microsomal S9 fraction[12] to indicate the role of metabolic activation.

Statistical Treatments

The creatinine, mutagenicity (reverse and forward +S9 or −S9), thioether, and D-glucaric acid data were stratified in terms of smoking status. Chi-square tests for normality of raw and log-transformed data were used to indicate the appropriate representative values to be calculated.[30] Arithmetic means and standard deviations were computed for data obeying a normal distribution, whereas geometric means and geometric standard deviations were calculated for lognormal distributions. Analysis of variance (ANOVA) techniques allowed significant differences and interactions to be determined[30] relative to anticancer drug exposure and smoking status. Nonparametric tests and regression correlational analyses were used as appropriate.

Results

There was no statistically significant age difference between the oncology nurses (age range = 24 to 54 years, average age = 36 years) and the controls (age range = 23 to 61 years, average age = 40 years). Forty-six percent of the latter and 25% of the former were smokers.

Direct observation revealed the following potential exposure situations.

- During preparation: Powder particles and liquid droplets aerosolize. Also, spills, leaks, and container/syringe breakage occur during transport from or to the pharmacy or during shaking.
- During administration: Syringes leak during transport, priming of intravenous sets, expelling of air, and connection to or removal from the patient. Aerosols form during priming, expelling of air, and connection to or removal from the patient.
- Miscellaneous exposures. Discarded containers contaminate housekeeping workers. Also, improperly cleaned equipment/containers and patient excreta are sources of contamination.

Individual Tests' Results

Reverse mutation assay. Of 19 oncology nurses, 3 produced urine mutagenic with strain TA1535 +S9 or −S9 and with TA98 −S9 (Table 1). None of 19 control nurses had urine mutagenic with TA1535 +S9 or −S9; 5 of 11 control group smokers had urines slightly mutagenic with strain TA98 −S9 but not on dilution. The data were lognormally distributed.[30] The sensitivity, specificity, and efficiency proportions, assuming that all oncology nurses absorbed anticancer drugs, were 16%, 100%, and 58%, respectively. The test was very specific but insensitive.

Forward mutation assay. Mutagenicity in the absence of S9 was found for 13 of 15 nonsmokers and all 6 smokers in the oncology nurse group (Table 2). In the control nurse group, 8 of 10 nonsmokers and 8 of 11 smokers had mutagenic urine. The values of sensitivity, specificity, and efficiency, assuming that the oncology nurses absorbed anticancer drugs, were 90%, 23%, and 57%, respectively. The test was sensitive but not very specific.

In +S9 assays for oncology nurses, 2 of 15 nonsmokers and 4 of 6 smokers had mutagenic urine. For the controls, 5 of 10 nonsmokers and 4 of 11 smokers had mutagenic urine. The sensitivity, specificity, and efficiency proportions were 29%, 52%, and 43%, respectively, assuming that the oncology nurses absorbed anticancer drugs.

All data were lognormally distributed.[30] Dose responses on dilution were observed only in S9 absence.

Creatinine. Nonparametric ANOVA on ranks showed no significant differences ($P < .05$) between the averages of the data for the two nurse populations or between smokers and nonsmokers; also, there were no interactions between exposure and smoking status. Five oncology nurses and two controls had dilute[31] urines less than 2.65 mM.

D-Glucaric acid. The nonparametric median test for 19 oncology nurses and 22 control nurses showed no significance ($P < .05$) between the number of nurses above the total group median, regardless of smoking status. Three oncology nurse urines exceeded the highest control value. Concentrations for US females range from 20.2 to 42.0 μmol/g creatinine.[11] Assuming that anticancer drugs were

absorbed by all oncology nurses, the sensitivity, specificity, and efficiency values of the test relative to the 42 μmol/g creatinine upper reference limit were 33%, 67%, and 50%, respectively.

Thioethers. There was no statistical difference ($P < .05$) between the group means of control nurses and of oncology nurses, regardless of smoking status. No oncology nurse urine exceeded the highest thioether concentration for the controls. The recommended upper limit[28] is 5.9 mmol thiols(−SH)/mol creatinine. Two control nurses exceeded this limit. Assuming that the oncology nurses absorbed anticancer drugs, the sensitivity, specificity, and efficiency proportions relative to the 5.9 mmol −SH/mol creatinine upper reference limit were 0%, 92%, and 46%, respectively. The test was specific but not sensitive.

Marker cross comparison. There were no correlations (Pearson $P < .05$) between any of the markers relative to smoking status, except individually for the three oncology nurses whose urines exhibited reverse mutation. There were also no correlations between marker concentrations and work practices. Smoking alone does not explain the incidence of forward mutations. S9 addition increases the specificity of the forward mutation assay.

One oncology nurse's urine had high glucaric acid and relatively high thioethers (5.68 mmol −SH/mol creatinine) and showed forward and reverse mutation with TA98 before dilution. She also probably absorbed antineoplastic drugs. Thus, only four oncology nurses excreted enough of these drugs to be detected by this battery of markers.

Discussion

This study is the first to report forward mutation assay data for oncology nurses handling anticancer drugs. The assay was sensitive but nonspecific in the absence of S9. Addition of S9 caused greater specificity but markedly decreased sensitivity.

Use of the marker battery was no great advantage as a screening tool relative to the reverse mutation assay alone, since only one extra oncology nurse was judged to have absorbed anticancer drugs.

The mutagenicity data were lognormally distributed for these weakly mutagenic spot urines. Some investigators have assumed that their data are distributed normally.[17,25] A lognormal distribution describes the incidence of micronuclei in human blood peripheral lymphocytes exposed in vitro to adriamycin and cyclophosphamide in urines and exposed to 24-hour urines from patients given high doses of anticancer drugs.[13] At high mutagen concentrations, as found for concentrated 24-hour urines, the data are distributed normally.[12]

The lack of correlation between work practices and detection of urinary mutagenicity was surprising. The absolute sensitivity of the reverse mutation assay is more than adequate to detect mutagens in urine.[1–4,7–12,15–26]

The sensitivity of the urinary mutagenicity marker for these spot urine samples is, however, dependent on the pharmacokinetics of the drugs. Urinary mutagenicity for chemicals of short body half-times (e.g., cyclophosphamide) after intravenous injection will provide information about same-day or recent exposures. Cyclophosphamide was not detected in these urines, since addition of S9 did not result in the expected enhanced mutagenicity for strain TA1535.[12] Conversely, exposures to drugs of long body half-times such as adriamycin[1–3,15] will not be correlated to recent exposures. The whole body half-time after skin exposure is generally much longer than after oral or intravenous dosing. This suggests that 12- or 24-hour urines should be collected instead of spot samples.

Skin absorption is the major route of anticancer drug exposure.[4,5] The rate and efficiency of absorption is a function of skin location, exposure time, skin exposure area, the presence and protective efficiency of gloves and garments, skin blood perfusion, and the thickness of fat layers under the epidermis.[15] Since most of the anticancer drugs are administered in aqueous solution, long body half-times are expected, even for chemicals of short body half-time when injected intravenously, since intact skin is protective against hydrophilic and very polar molecules.[15] Thus, the time and duration of urine sampling may be crucial to the detection of these urinary mutagens as well as of the other urinary markers. This may explain the general insensitivity of the entire battery of markers (apart from the nonspecific forward mutation assay in the absence of S9) and why mutagenicity did not correlate with potential exposure events on the same day. Thioethers are also known to increase some time after anticancer drug exposure.[32–34]

The self-reported information in the nurse work logs was also not detailed enough to enable assessment of the intensity and duration of any direct exposure of the skin. This is not surprising since nurses are very busy and instant recording is difficult. Later recall of spills under such conditions would be even worse. This suggests that experienced observers who know how to account for the effectiveness of protective equipment must be used to estimate exposure extent. This should be done in future studies.

The reverse mutation assay is the most sensitive and specific assay to detect urinary mutagens after antineoplastic drug exposure. More research is necessary to determine how skin exposure correlates to urinary mutagenicity and when and for what duration urine sampling should be performed after dermal exposure. □

The Consumption of Well-Done Red Meat and the Risk of Colorectal Cancer

Joshua E. Muscat, MPH, and Ernst L. Wynder, MD

ABSTRACT

Heterocyclic aromatic amines and polycyclic aromatic hydrocarbons are mutagens that are produced in highly cooked meats. A case–control study of 511 patients with colorectal cancer and 500 matched control subjects examined whether consumption of well-done cooked beef is related to the risk of developing large bowel cancer. Approximately 16% of men and women consumed well-done beef, and 50% ate medium-cooked beef. For both sexes, there was no association between consumption of well-done or medium-cooked beef and colorectal cancer. This paper discusses whether questionnaire data accurately reflect dietary intake of heterocyclic aromatic amines and polycyclic aromatic hydrocarbons. (*Am J Public Health.* 1994;84:856–858)

Introduction

Heterocyclic aromatic amines and polycyclic aromatic hydrocarbons are mutagens that are formed during high-temperature cooking of red meat and, in lesser amounts, white meat and fish.[1] Well-done meat contains 10 times the concentration of heterocyclic aromatic amines than rare meat prepared by the same cooking method.[2] These amines are mutagenic in bacterial assays[3] and have produced colon tumors in laboratory animals.[4]

Only a few epidemiological studies have examined the association between cooked red meats and colon or rectal cancer. In a prospective study of 89 000 US nurses, Willett et al.[5] reported no association between cooked red meat that was consumed daily and colon cancer; however, they provided no data. In a case–control study, Lyon and Mahoney[6] found no relationship between consumption of broiled or fried meats and colon cancer. In contrast, a Swedish case–control study of colorectal cancer found an increased risk with total meat intake and a preference for heavily browned meat surface.[7] Schiffman and Felton[8] postulated that the degree of doneness of red meat may be an important indicator of heterocyclic aromatic amine intake, and they provided preliminary results from a case–control study of colorectal cancer (n = 50 cases) that showed a significantly increased risk among subjects who consumed well-done red meat. We examined the association between the consumption of well-done beef and colorectal cancer using data from a large case–control study.

Methods

Five hundred eleven patients with histologically confirmed primary cancer of the large bowel (346 with colon cancer, 165 with rectal cancer) were interviewed between 1989 and 1992 in five hospitals. Control patients included 500 subjects matched randomly with each patient by sex, race, hospital, age (within 5 years), and time of the case interview (within 2 months). Eligible control patients included patients with conditions unrelated to dietary fat and fiber intake, such as joint replacement (9.1%), injuries (8.7%), benign prostatic hyperplasia (7.9%), some musculoskeletal disorders (6.7%), melanoma (4.8%), benign skin diseases (4.0%), ill-defined symptoms (3.6%), renal calculus (3.2%), and hernia (2.8%). The pathology reports of the cases were examined to determine the site and stage of the tumor. More than 90% of both case and control patients who were approached participated in the study.

Data on sociodemographic characteristics, medical history, analgesic use, family history of cancer, smoking, alcohol use, physical activity, vitamin use, and dietary history were collected using a standardized questionnaire administered by trained interviewers. The food frequency section included questions on the major sources of total dietary fat and fiber. For the red meat questions, patients were asked how many times they ate "beef, steaks, roasts or hamburgers" per day, week, or month "during the longest period of your adult life," and whether they ate their beef "well-done, medium or rare."

Relative risks of colorectal cancer associated with well-done beef were calculated using the ratio of discordant case–control pairs for men and women.[9] Chi-square analysis and 95% confidence intervals (CIs) were calculated to test statistical significance.

Results

Table 1 presents basic sociodemographic characteristics of the study subjects. Case and control patients had similar ages and years of education. A higher proportion of female control pa-

tients than of female case patients were never married. Male control patients were more likely to have been Jewish and less likley to have been Catholic than male case patients. Approximately 50% of men and women in both groups combined ate medium-cooked beef, and 16% had their beef cooked well-done. The frequency of beef consumption and other potential risk factors were unrelated to the degree of doneness.

Among men, the relative risks for colorectal cancer were 1.15 for consumption of well-done beef (95% CI = 0.6, 2.4) and 1.00 for consumption of medium-cooked beef (Table 2); for rectal cancer only, the relative risk for well-done beef was 2.0 (95% CI = 0.7, 5.9). For women, the relative risks for colorectal cancer were 1.00 for consumption of well-done beef and 0.95 for consumption of medium-cooked beef, with no differences in risk between the colon and the rectum.

Discussion

International correlations between per capita consumption of meat and colorectal cancer rates, as well as epidemiological studies of dietary fat intake, have implicated fat in colon cancer carcinogenesis.[10] Schiffman and Felton[8] suggest that these correlations may actually reflect intake of heterocyclic aromatic amines. If both fat and amine intake are risk factors for large bowel cancer, then isolating the effects due to amine intake may be difficult in epidemiological studies. The fat content of red meat diminishes with the amount of cooking. Well-done beef contains 36% fat by weight, whereas rare or raw beef contains more than 50% fat according to one study.[11] Therefore, the potentially higher risk associated with well-done beef may be counterbalanced by the lower fat content of the meat. On the other hand, low-quality beef with higher fat content is usually cooked more thoroughly than prime cuts and with additional sauces or gravy (which may also contain fat and heterocyclic aromatic amines) to add flavor and texture.

The content of heterocyclic aromatic amines in beef increases substantially with frying time,[12] suggesting that substantial amounts of amines are present only in well-done beef. Schiffman and Felton[8] report that subjects who consumed well-done beef had a 3.5-fold (95% CI = 1.3, 9.6) increased risk of developing colorectal cancer compared with subjects who ate "rare to medium rare" red meat. The study by deVerdier et al.[7] shows that consumption of heavily browned meat increases the risk of colorectal cancer. Lyon and Mahoney[6] found no significant associations between consumption of broiled or fried meat and risk of colon

Well-done	12	15	8	1.00	. . .

Note. Double-underlined numbers are the discordant pairs for well-done meat. Single-underlined numbers are the discordant pairs for medium-done meat. Table excludes subjects who did not have a matched pair or whose pair did not eat red meat.
[a]Reference category. An unmatched analysis yielded the same results.

cancer. These discrepant study findings may reflect differences in the method of cooking beef (e.g., frying and broiling vs baking) and in the amount of well-done beef consumed. There are little population-based data on beef cooking habits, although one case–control study of 7860 subjects found that men and women ate meat approximately 22 and 18 times per month, respectively,[13] compared with 13 and 11 times per month, respectively, in this study. The lack of an association in our study may reflect a relatively low intake of highly cooked beef.

Questions on meat consumption frequency tend to have low reliability.[14,15] It seems intuitive that subjects would respond more accurately to questions on beef doneness, but this needs to be verified. In the Swedish colorectal cancer study (n = 559 cases), a significant risk was found for high "temperature when frying" and "heavily browned" meat surface,[7] although these definitions may be especially prone to subjective responses. In the study by Schiffman and Felton,[8] a significant risk was found for well-done red meat compared with both red meat cooked "medium to well" and rare red meat, yet the actual difference in heterocyclic aromatic amine intake between "well-done" and "medium to medium-well" meat may be slight. Further research in this area should consider the opposing risks of a higher amine amount but lower fat content in well-done beef and other meats, and should determine the reliability and validity of questions on meat cooking habits. □

Cancer Control Career Development Award for Primary Care Physicians

The American Cancer Society is pleased to announce the 1995 Cancer Control Career Development Award for Primary Care Physicians. This award is intended to develop academic leaders in primary care specialties emphasizing cancer control: family practice, general internal medicine, obstetrics and gynecology, and pediatrics. Through the award, the Society seeks to support individuals in supervised programs that will develop the candidate's clinical and teaching expertise and his or her capacity to perform independent clinical research in cancer control. It is anticipated that physicians trained under these awards will improve cancer control through involvement in primary care practice, education, and research activities related to cancer control.

This is a 2-year award. The stipend for the award is $25 000 for the first year and $30 000 for the second. Candidates for first-year awards may not have an academic rank above that of assistant professor and must not be tenured or be the section head (or equivalent) in their discipline. These awards are intended to support the early development of academic careers that place emphasis on cancer control; physicians with well-established careers and substantial research funding should not apply. In addition, candidates for these awards must be citizens or permanent residents of the United States.

The application deadline is August 15, 1994, for awards to begin July 1, 1995. For brochures, applications, and further information, please contact the office of Virginia Krawiec, MPA, Detection and Treatment Department, American Cancer Society, Inc, 1599 Clifton Rd, NE, Atlanta, GA 30329-4251; tel (404) 329-5734; fax (404) 325-1467.

Outbreak and Sporadic Egg-Associated Cases of *Salmonella enteritidis:* New York's Experience

Dale L. Morse, MD, MS, Guthrie S. Birkhead, MD, MPH, Joanne Guardino, MS, Stanley F. Kondracki, and John J. Guzewich, MPH

ABSTRACT

Since 1985, egg-associated *Salmonella enteritidis* has emerged as a major cause of foodborne disease. New York State has been especially affected, with 47 documented egg-associated *S enteritidis* outbreaks involving 2279 cases and 10 deaths. Individual case reports of salmonella have also increased 56%, and sporadic cases of *S enteritidis* have been shown to be associated with egg consumption. Further educational and regulatory activities are needed to control this continuing public health problem. (*Am J Public Health.* 1994;84:859–860)

Introduction

During the recent epidemic of *Salmonella enteritidis,* New York State has been particularly affected, having been the site of some of the earliest, largest, and greatest number of outbreaks.[1–3] Between 1985 and 1993, New York documented 253 salmonella outbreaks, of which 89 (35%) were due to *S enteritidis* (Table 1). Of the latter, 47 (53%) were egg associated, and these outbreaks resulted in at least 2279 cases and 10 deaths. Concurrently, the number of total salmonella cases reported through the state's notifiable disease surveillance system for upstate New York (excluding New York City) increased from 1513 (14.5 per 100 000) in 1984 to more than 2366 (21.9 per 100 000) in 1993 (provisional data).

Surveillance Efforts

The large number of *S enteritidis* outbreaks made it likely that a number of sporadic cases were also associated with eggs.[1,2,4] Two reports in the literature from the United Kingdom supported that conclusion.[5,6] More recently, Hedberg et al.[7] showed that persons with sporadic cases of *S enteritidis* (odds ratio [OR] = 5.2) and *Salmonella typhimurium* (OR = 2.4) were more likely than controls to have consumed undercooked eggs or egg-containing foods. We conducted a limited pilot study of risk factors for sporadic *S enteritidis* cases identified in three New York counties (Erie, Onondaga, and Monroe). During an 8-month period in 1989, additional surveillance information was collected on all adults with reported non–outbreak-associated, culture-confirmed salmonella and campylobacter cases who could be interviewed within 14 days of illness onset. Data were obtained for 45 cases of *S enteritidis* and compared with those for 316 cases of campylobacteriosis and 156 cases of non–*S enteritidis* salmonellosis (55 *S typhimurium,* 21 *Salmonella heidelberg,* and 80 other salmonella species). Results showed an association between illness and egg consumption within 3 days of illness for cases of *S enteritidis* relative to cases of campylobacteriosis and a borderline association relative to non–*S enteritidis* salmonella cases (see Table 2).

Conclusions

These studies' findings indicate that the number of illnesses related to consumption of raw or undercooked eggs is far greater than recognized by outbreak surveillance alone. This helps explain the failure of current US Department of Agriculture control practices, which are based on testing of laying flocks only if they are conclusively linked to an outbreak and identified through a traceback or are found on a voluntary testing basis.[8,9]

In response to the increase in *S enteritidis,* the New York State Department of Health has adopted regulations requiring the refrigeration of eggs in food service establishments and the cooking of all eggs and foods that contain eggs to 145°F (unless prepared differently at the request of a consumer). It has also recommended that recipes containing raw eggs (e.g., mayonnaise, Caesar salad dressing, and eggnog) be considered high risk and that pasteurized eggs be used for these preparations as well as in institutions serving high-risk populations (e.g., hospitals and nursing homes). Eggs are a highly nutritious food but must be cooked thoroughly; consumption of raw eggs, like raw milk, raw shellfish, and raw meat, can be a health hazard. In the absence of an effective control program, the Depart-

The Reproducibility of Data from a Food Frequency Questionnaire among Low-Income Latina Mothers and Their Children

Charles E. Basch, PhD, Steven Shea, MD, and Patricia Zybert, PhD

ABSTRACT

We examined the 3-month and 1-year reproducibility of mothers' and children's dietary intakes of calories and 11 nutrients derived from oral administrations of a food frequency questionnaire to 166 Latina women. One-year correlations generally ranged from 0.40 to 0.55 for both mothers and children. For most nutrients, roughly half the children in the highest (lowest) quartile of intake at baseline were also in the highest (lowest) quartile 1 year later. The food frequency questionnaire has great potential for measuring typical nutrient intakes in these populations. (*Am J Public Health.* 1994;84: 861–864)

Introduction

Reliable, valid, and practical measures of typical diet are needed for public health research.[1] Dietary recalls may accurately estimate nutrient intakes,[2,3] but large day-to-day variations in diet[4] necessitate multiple labor-intensive administrations to measure individuals' typical intakes.[4–6] Single administrations of a food frequency questionnaire have yielded acceptably reliable and inexpensive estimates of typical intake for a range of nutrients in various contexts.[5] Thus, despite limitations,[5–8] food frequency questionnaires have become the primary tool for dietary measurement in epidemiological studies.[5] We report 3-month and 1-year reproducibility of mothers' and children's dietary intakes of calories and 11 nutrients derived from oral administrations of a food frequency questionnaire to 166 Latina women. Reproducibility of nutrient intake estimates derived from food frequency data has not been reported previously for these groups.

Methods

Subjects and Setting

Subjects were 166 Latina mothers participating in a longitudinal study of generally healthy, low-income families living in New York City (Table 1). Subjects reported on both their own and their children's dietary intake on at least three occasions, using a modified version of the Willett food frequency questionnaire. Details of recruitment and eligibility have been published previously.[4,9,10] Mean ages of the mothers and their children at baseline were 33.3 years (SD = 5.1) and 5.4 years (SD = 0.4), respectively. Half the children were female.

Measurements

Modified Willett food frequency questionnaires[5,11] were administered to mothers three times for their own intakes and three times for their children's intakes over a 1-year period. Bilingual interviewers read a list of foods to mothers and, in a closed-response format, recorded the frequency with which each food was consumed.[5,11] The list included ethnic foods not on the original questionnaire and omitted foods originally listed but never eaten by this population. Children's portions were reduced to be consistent with portions reported in 24-hour dietary recalls from the same population.[2,4] The questionnaire's original 1-year time referent was reduced to 6 months. Nutrient intakes were computed using a database and program provided to us by Willett (W. Willett, MD, DrPH, personal communication, 1986, updated 1989), which we altered to match our food lists.

Statistical Analysis

Test-retest Pearson correlations were computed, and values for mothers versus children and for 3 months versus 1 year were compared using the *z* test applied to Fisher's *z* transformed correlations.[12] Since caloric adjustment of nutrient intakes[5,13,14] did not systematically affect reproducibility for the 11 nutrients, only results for unadjusted nutrient intakes are presented (Table 2). Regression equations and correlations were calculated after logarithmic transformation of intakes. The proportions of mothers and children consistently classified into the lowest and highest quartiles of caloric and nutrient intake over 1 year were also determined.

Results

Table 2 presents untransformed mean intakes of calories and 11 nutrients for

mothers and children at baseline. Nutrient intakes derived from multiple 24-hour recalls on the same children[10] suggest substantial inflation in the food frequency–derived estimates.[15,16] Table 3 presents 3-month and 1-year test-retest correlations. Disregarding densities, 3-month correlations among mothers ranged from .45 for vitamin B6 to about .60 for polyunsaturated fat, crude fiber, total fat, calories, carbohydrates, and vitamin A. Among the children, the 3-month correlations ranged from −.06 for sucrose to more than .50 for crude fiber, total fat, carbohydrates, calories, polyunsaturated fat, cholesterol, and vitamin A. One-year correlations among mothers ranged from .35 for vitamin B6 to more than .5 for crude fiber, carbohydrates, and calories. The 1-year correlations for children were similar, except that children's sucrose intake was less stable at 1 year than their mothers' ($z = 4.3, P < .01$). Reproducibility over the shorter interval tended to be higher for both mothers and children. For most nutrients, approximately half the mothers and children in the highest (lowest) quartile of intake at baseline were also in the highest (lowest) quartile 1 year later (Table 4).

Discussion

Latino people and groups with low income have been designated as special target populations in many diet-related health objectives for the year 2000.[1] Compared with higher income non-Hispanic Whites, low-income Hispanics have higher triglycercide levels,[17,18] lower high-density lipoprotein cholesterol levels among women,[17] increased prevalence of diabetes[19–23] and obesity,[17,23,24] and higher Framingham cardiovascular risk scores.[24] Reliable, valid, and practical dietary measures for use in these populations are needed to monitor diet-related risk reduction goals.[1,25–31]

Our 1-year test–retest correlations for mothers' intakes based on a single, orally administered food frequency questionnaire generally ranged between .40 and .55. In Willett's study of 173 women in the Nurses Health Study, 1-year

Pearson correlations ranged from .50 to .65 for most unadjusted nutrients.[11] However, ethnic, social, and behavioral differences should be considered when comparing these studies. The acculturation process may produce greater instability of dietary intake among our immigrant population. Low-income non–English-speaking women may have different body weight norms[32] and correspondingly different levels of attentiveness to the details of their diet than the health professionals studied by Willett et al.[11] Also, the women in our study may have been less prepared to respond to the structured questions typical of standardized data collection protocols. Finally, our changing of the time referent from 1 year to 6 months may have reduced reproducibility by introducing seasonal variation.

Some studies support the value of surrogate reports for measuring diet[2,3] while others document shortcomings.[33,34] We found that a single food frequency questionnaire administered orally to mothers provided 1-year and 3-month test-retest correlations for children's intakes generally ranging between .40 and .55 and between .45 and .55, respectively. Treiber et al. observed 1-week test-retest correlations for 55 children from middle socioeconomic class families that were generally between .50 and .70[35]; their higher correlations are compatible with the shorter time interval. Eck et al. report average 4- and 8-month test-retest correlations for 108 young children from intact families generally in the range of .60 to .65.[36] Our data[10] as well as those of Treiber et al.[35] indicate that food frequency questionnaires yield inflated estimates of children's absolute intakes.

While a single 24-hour recall may provide valid intake estimates for a single day, these estimates are not reproducible because of day-to-day variations in an individual's diet.[4] Thus, a single recall does not measure typical diet. In contrast, food frequency questionnaires may yield inflated estimates of absolute intakes, but they are presumably reproducible because they reflect typical diet. This paper does not address the validity of food frequency–derived estimates. Further research is needed to calibrate the food frequency to yield more accurate data.

Several limitations of this study restrict the scope of conclusions that can be drawn. First, we cannot generalize to nutrients we did not examine. Second, we did not identify or control variations in food availability or accessibility, either of which might have confounded our results.

TABLE 4—Proportions of 166 Mothers and Children Classified into Lowest (Highest) Quartile of Caloric and Nutrient Intakes at Baseline Who Remained in Lowest (Highest) Quartile or Half 1 Year Later

	Mothers				Children			
	Lowest Baseline		Highest Baseline		Lowest Baseline		Highest Baseline	
	Lowest Quartile	Lower Half	Highest Quartile	Higher Half	Lowest Quartile	Lower Half	Highest Quartile	Higher Half
Calories	.51	.80	.51	.76	.46	.80	.44	.73
Protein, g	.39	.76	.49	.76	.54	.80	.46	.66
Total fat, g	.56	.78	.54	.78	.41	.80	.54	.80
Total fat, % of calories	.54	.78	.46	.61	.32	.71	.59	.83
Saturated fat, g	.54	.83	.46	.78	.49	.80	.41	.71
Saturated fat, % of calories	.49	.73	.41	.68	.49	.66	.29	.68
Polyunsaturated fat, g	.41	.78	.49	.80	.51	.80	.51	.80
Cholesterol, mg	.34	.63	.49	.68	.41	.76	.46	.71
Cholesterol/1000 kcal	.51	.68	.37	.63	.46	.73	.41	.59
Carbohydrates, g	.63	.83	.43	.79	.49	.85	.39	.68
Sucrose, g	.54	.83	.27	.63	.46	.78	.44	.68
Crude fiber, g	.54	.76	.51	.85	.59	.88	.56	.83

Vitamin B6, mg	.36	.67	.49	.73	.40	.67	.39	.76
Vitamin C, mg	.51	.68	.41	.63	.41	.66	.32	.59

Third, we did not have a gold standard and could not distinguish true change in diet from measurement error. Fourth, we could not determine the specific sources of measurement errors.

We view our results as encouraging. Our 1-year reproducibility of food frequency–derived nutrient intakes for both mothers and children was only slightly lower than the published reproducibility[11] at which the food frequency questionnaire has been found to be a useful tool for epidemiological research.[5,11] When using the current version of the Willett food frequency questionnaire among low-income non–English-speaking adults, we recommend oral administration coupled with enhancement of stability through averaging of the results from multiple administrations. Analyses involving children's absolute intakes should be avoided. Following these guidelines, we have found relationships between ordinal classification by children's saturated fat intake and serum lipids[9] and between mothers' food choice beliefs and children's nutrient intakes.[37] Both of these results were confirmed using nutrient intakes derived from multiple 24-hour recalls.[9,37] Research is needed to identify the sources of instability in food frequency measurements and, for children, to determine the factors that result in inflated intake estimates. □

Acknowledgments

This research was supported in part by grants from the National Heart, Lung, and Blood Institute (HL-35189 and HL-49508) and the Cancer Research Foundation of America. At the time of the study, Steven Shea was a Florence Irving Assistant Professor.

The *American Journal of Public Health* (*AJPH*), published monthly, is the official Journal of the American Public Health Association, Inc, 1015 15th St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $13 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005. *AJPH* allotted $40; *The Nation's Health* allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters. Printed in the United States.

Advertising Sales: Maureen Sheridan, Advertising Manager, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on the first page of published article. For cost information on 100 or more reprints, contact Marilyn Butler, *AJPH* Reprints, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the Journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

Rationing or Rationalizing Children's Medical Care: Comparison of a Medicaid HMO with Fee-for-Service Care

Jane Mauldon, PhD, Arleen Leibowitz, PhD, Joan L. Buchanan, PhD, Cheryl Damberg, MPH, and Kimberly A. McGuigan, MS

ABSTRACT

Objectives. This paper examines how medical care obtained by children enrolled in a Medicaid health maintenance organization (HMO) differs from that obtained by similar children who receive care from fee-for-service Medicaid providers.

Methods. In a randomized trial, some Medicaid households were assigned to remain in a traditional fee-for-service arrangement and others were randomly selected to join a Medicaid prepaid plan (an HMO). Participating households recorded data on children's health status and use of medical care.

Results. The prepaid plan members and the fee-for-service recipients received equivalent numbers of checkup visits, but the children in the prepaid plan made significantly fewer acute care visits. This plan appeared to target its services to children with the greatest health care needs. However, the content of health visits in the two systems did not differ, nor did prepaid and fee-for-service enrollees use the emergency room differently.

Conclusions. It is possible to design a Medicaid HMO that achieves financial savings without reducing services to the most vulnerable patients. However, these findings alone do not provide a basis for widespread policy change in the direction of Medicaid HMOs. Further research is needed to establish whether the children treated in the HMO differed in health outcomes from those treated by fee-for-service care. (*Am J Public Health.* 1994;84: 899–904)

Introduction

In recent years, policymakers and the research community have been discussing structural reforms for the Medicaid program that would control costs without creating further access barriers to patients. Enrolling Medicaid beneficiaries in health maintenance organizations (HMOs) instead of paying for their care on a fee-for-service basis is one of the most common proposals. However, it is important to determine whether the HMO's rationing of care further reduces access to needed services, or whether HMOs reduce costs by "rationalizing" service delivery to provide care for those with greatest needs while eliminating unnecessary services.

Given the considerable policy interest in HMOs, the Robert Wood Johnson Foundation, under its Program for Prepaid Managed Health Care, funded 13 demonstration projects in 1984 to expand the use of case management and capitation within the Medicaid population in 10 states across the country. The purpose of these experiments was to study the consequences of substituting HMO-type plans for traditional fee-for-service arrangements in the Medicaid program. The Health Care Financing Administration and the National Governors' Association joined the Robert Wood Johnson Foundation in sponsoring the RAND Corporation to evaluate these programs. This paper, part of the evaluation, reports data on children's use of outpatient care from one of the experimental sites.

Fee-for-Service Medicaid vs HMOs

The constraints and incentives that operate in fee-for-service Medicaid programs can generate inappropriate patterns of care for enrollees. One problem is that low Medicaid reimbursement levels discourage doctors from treating Medicaid patients, so many enrollees have limited or no access to private physician care. Consequently, many Medicaid patients seek care in hospital emergency rooms.[1–4] However, hospital emergency rooms are inappropriate sources of routine care because they provide episodic, high-cost services. Children who use such facilities as a regular place of care may not receive routine checkups and preventive care. Further, they may not receive *timely* care for incipient problems that would be noted and possibly treated during a checkup by a personal physician. Work by Kasper confirms that young children get more health care when they have a regular provider and not just a regular place of care.[5] HMOs have the potential to move the routine care of Medicaid beneficiaries out of hospital emergency rooms and into private physicians' offices, health centers, or outpatient clinics.

A second problem is that fee-for-service systems may induce excessive visits to private physicians while still not guaranteeing that patients receive all the medical care they need. When physicians are paid only for actual patient visits (and not, e.g., for telephone consultations), they may try to achieve adequate total reimbursement by encouraging multiple short visits for

This paper was accepted November 29, 1993.

simple problems. In contrast, HMOs and other providers under capitated payment systems seek to offer care in the most cost-effective ways, which may mean replacing patient visits with telephone consultations or using fewer visits to treat a problem. If this is in fact the outcome, using HMOs for Medicaid clients could improve care and reduce unnecessary use. However, prepaid plans present incentives to reduce use generally, which may discourage medically necessary patient visits and lead to underprovision of needed services.

Experimental Reforms in Medicaid

Policy interest in Medicaid HMOs has been translated into legislative action on several occasions. Section 2178 of the Omnibus Budget Reconciliation Act of 1981 broadened states' opportunities to contract with existing HMOs for Medicaid services, while section 1915 invited states to experiment with both new forms of prepaid care and new forms of case management for Medicaid enrollees (under waivers from the existing Medicaid legislation).

Programs established under section 1915 were of particular interest to the policy research community. Many of these programs were included in the Medicaid Competition Demonstration Project, a multisite research project to assess opportunities for Medicaid reform; findings from the project provide the backdrop for our findings reported below.

A quasi-experimental evaluation of programs in Monterey and Santa Barbara, Calif, and in Kansas City, Mo (which were all "mandatory"—i.e., beneficiaries did not have the option of remaining in the fee-for-service system), and of a voluntary program in New Jersey, found strong and pervasive effects of gatekeeping mechanisms on the likelihood of an emergency room visit. In all four programs, the gatekeeper (an individual physician or primary care organization) was required to provide all primary care. Prior authorization by the gatekeeper was required before enrollees could receive nonurgent emergency room care, inpatient care, or services from other physicians. The study compared use of the emergency room among stratified random samples of Medicaid beneficiaries drawn from the experimental counties and nearby comparison counties. Much smaller proportions of both children and adults used emergency room services at least once in the experimental sites. However, numbers of emergency room visits for persons with at least one such visit were less substantially affected by the plans.[6]

Bonham and Barber examined the effect of a mandatory HMO Medicaid program on usage through in-depth interviews with randomly chosen Medicaid recipients, both prior to the start of the program and 1 year into it.[7] They found a 40% reduction in (self-reported) use of hospital emergency rooms, apparently owing to less use of the facilities for nonurgent care. There was no change, however, in the rate of hospital inpatient stays, ambulatory care, or prescribed drugs.

Two of the nine programs for which there are published estimates of program effects failed to reduce emergency room use, in each case for quite specific and readily identifiable reasons. In one program, pediatric emergency room use had been relatively low at the outset (i.e., under the fee-for-service system), so there was not a lot of room for improvement. In addition, some of the emergency room use was unapproved by the case manager and consequently did not have to be paid for by Medicaid.[8] The other plan that failed to change patterns of emergency room use was hospital based, so the hospital may not have faced strong financial incentives to shift care from the emergency room to the HMO clinic because it ran both.[9]

Most evaluations of non-Medicaid HMOs have found that HMOs increase the number of outpatient visits relative to fee-for-service care.[10-12] This is because HMO patients face minimal or no cost sharing while fee-for-service patients must pay at least part of the cost for outpatient visits. For Medicaid patients, the situation differs. Neither the HMO nor fee-for-service Medicaid requires patient cost sharing. Thus, if Medicaid patients use more visits in HMOs, this would reflect improved physical access rather than greater affordability.

HMOs may not provide an ideal alternative for Medicaid patients since studies suggest that low-income patients may not fare as well in HMOs as middle-income enrollees. Ware et al. show that, in a randomized trial, low-income adults with preexisting health problems reported more serious health problems and more bed days per year when they were assigned to an HMO rather than to fee-for-service care.[13] Although a study of children in the same HMO assignment revealed no significant negative health effects for those of either low or middle income,[14] the Ware finding suggests the importance of examining this issue for Medicaid HMO enrollment.

The Children's Medicaid Program in New York compared use of services for children treated in one of three systems: (1) traditional fee-for-service Medicaid; (2) a fee-for-service Medicaid group with case management and augmented provider payments; and (3) a capitated, case-managed traditional HMO group with risk sharing for referred services. In their evaluation of this system, Hohlen et al. report that children in the capitated system received at least as much care as regular Medicaid children through the combination of physician office and outpatient clinic visits.[15]

While these studies suggest quite strongly that HMOs reduce emergency room use and may under some circumstances increase preventive use, they still leave many questions unanswered. In particular, the studies do not indicate which types of emergency room use are constrained by gatekeeping systems (although Bonham and Barber[7] provide some data on this) and which types of patients are most inclined to change their behavior when they enter an HMO. It does not appear that the studies controlled for such confounding factors as overall health status and existing health problems. Nor do these studies reveal whether or how children's patterns of care seeking change when they shift from fee-for-service to HMO systems. For example, is more change seen in routine visits or in acute visits? The study reported in this paper begins to fill some of these gaps in knowledge.

Our investigation examines three possible benefits of HMOs over fee-for-service Medicaid: (1) that HMO enrollees use emergency rooms less because the HMO makes primary care services more available; (2) that patients in HMOs have more checkup visits (partly because office-based care is available to them); and (3) that because preventive care is available, patients make fewer acute care visits. We test these hypotheses for pediatric services only.

Methods

Data

The data used here are from a randomized clinical trial in which some Medicaid households were assigned to remain in a traditional fee-for-service arrangement, others were randomly selected to join a Medicaid HMO, and still

others self-selected into either fee-for-service or HMO care.

The study HMO was situated in a hospital that was the primary Medicaid health provider for the area. Patients' access to services was better under the HMO than under fee-for-service Medicaid because patients had a case manager and could make appointments for specific times rather than being scheduled for 3-hour "block appointments."

Focusing exclusively on use of care by children, this investigation uses three types of data: characteristics of children and their families (obtained from baseline interviews), Medicaid eligibility and health plan enrollment data (obtained from administrative records), and use of care in a given 2-month period (recorded in diaries administered at baseline and 2 and 4 months thereafter). The use data come from mothers' diary reports of their children's health care use. The diaries are relied upon because, unlike the claims files, they distinguish well care visits from acute care visits. The 1867 children's diaries available for this analysis cover children aged 0 to 14.

TABLE 1—Outcome Measures, Demographic Characteristics, and Plan Status Variables

	Mean	SD
Dependent variables		
Percentage with checkup visit	24.7	0.43
Percentage with acute care visit	18.7	0.39
Percentage with emergency room visit, given any visit	12.7	0.33
Independent variables		
Child's age, y	6.2	3.74
Plan status, %		
Enrollees in HMO plan	51.0	0.50
Randomly assigned	53.7	0.50
In HMO plan and randomly assigned	21.1	0.41
Questionnaire timing, %		
Summer (April to September)	32.5	0.47
First wave	21.0	0.41
Second wave	66.5	0.47
Third wave	12.5	0.33
White (i.e., non-Hispanic, non-Black), %	13.0	0.34
Number of health problems reported per child at start of experiment		
Allergies	0.20	0.49
Serious health problems	0.01	0.09
Other health problems	0.30	0.64

Note. No. of diaries = 1867; no. of individual children = 1685.

The sampling frame was constructed from Medicaid eligibility files, including only those families eligible for Medicaid by virtue of eligibility for Aid to Families with Dependent Children. From the set of eligible families who currently received care in the fee-for-service Medicaid system, two subsamples were drawn. One was labeled the random assignment group and the other was the self-select group. Families in the first group were asked to agree to be randomly assigned to either receive their care in an HMO or continue to receive fee-for-service care. Thus, these families were comparable in that they all agreed, in principle, to enroll in an HMO if they were randomly assigned to do so. The actual plan assignment was not disclosed to random assignment families until after they had agreed to participate in the study. To determine whether families who agreed to randomization differed systematically from the average family enrolled in Medicaid, another sample of families who had fee-for-service Medicaid was selected and asked to enroll in the study but was not asked to agree to randomization (the second subsample). A self-selected HMO sample was chosen from the families with at least one member already in the study HMO plan at the time of the baseline interview.

Families that could not be located, either because their Medicaid records listed post office boxes rather than residential addresses or for other reasons, and families that spoke little or no English were excluded from the study. Any family belonging to a prepaid plan other than the study HMO was also ineligible.

Although families were informed that their enrollment in the study was voluntary, participation rates were high. Of the eligible sample, 80% (4433 of 5542 individuals) agreed to participate and 75% were actually enrolled. That is, only 268 people refused to participate after the initial informed consent. Families who did not enroll were not assigned to another group. There were no significant differences in average prior monthly Medicaid use between those whom the study located and those who were not located, between those who were eligible for enrollment and those who were ineligible, or between those who refused informed consent and those who accepted it. Neither did these groups differ significantly in terms of family size, average age, or percentage female, with the one exception that family size was larger in the eligible group (3.7) than in the ineligible group (3.4). Finally, the refusal rate was as low among random assignment families as it was among the self-select families.

Models

Three different dependent variables were examined, each one describing a sample child's use of health services during the 2-month period covered by the diary. These variables are whether the child (1) had a "regular" or checkup visit, (2) had a visit for acute care, and (3) visited an emergency room. There were up to three diaries for each child, each covering a different 2-month period. Analyses include a variance component correction to control for correlation among observations for a particular child. Logistic regressions were used throughout. Emergency room visits were modeled as conditional on having made any visit. The independent variables were selected based on previous studies of child health. Both dependent and independent variables are listed in Table 1.

In addition to plan status (in HMO or fee-for-service care), the explanatory variables include sex, race/ethnicity, age and age squared, and number of health problems. The distributions of most variables are unremarkable: there are a few more boys than girls, the average age of the children is 6, and relatively few existing health problems are reported (on average, about one condition in every two children).

About 13% of the children were described by their parents as White, 80% as Black, and about 5% as Hispanic. Because a large but unidentifiable number of Caribbeans (some of whom might have been classified as Hispanic) reported

TABLE 2—Determinants of Checkup and Acute Care Visits by Children Enrolled in a Medicaid HMO or in Medicaid Fee-for-Service Care: Odds Ratios and 95% Confidence Intervals (CIs)

	Type of Visit			
	Checkup[a]	Acute	Checkup[b]	Acute
	Odds Ratio (95% CI)	Odds Ratio (95% CI)	Odds Ratio (95% CI)	Odds Ratio (95% CI)
Enrolled in HMO plan	1.00 (0.72, 1.38)	0.72 (0.52, 1.01)	...	...
Enrolled in HMO plan, had no preexisting health problems			0.97 (0.69, 1.36)	0.65 (0.44, 0.95)
Enrolled in HMO plan, had at least one preexisting health problem	...	...	1.01 (0.74, 1.37)	1.08 (0.83, 1.39)

[a]Columns 1 and 2 contrast all HMO enrollees with all fee-for-service enrollees.
[b]Columns 3 and 4 contrast HMO enrollees with chronic conditions and HMO enrollees without chronic conditions with fee-for-service enrollees.

TABLE 3—Determinants of Emergency Room Visits by Children Who Used HMO or Fee-for-Service Medical Care: Odds Ratios and 95% Confidence Intervals (CIs)

	Odds Ratio	95% CI
Enrolled in HMO plan	1.06	0.62, 1.80
Randomly assigned	1.17	0.65, 2.11
Female	1.07	0.69, 1.65
White	1.15	0.52, 2.58
Child's age in years	0.80	0.64, 1.01
Child's age squared	1.02	1.00, 1.04
Total number of health problems listed as start of experiment	1.13	0.92, 1.39
Diary is from second wave	0.50	0.25, 0.99
Diary is from third wave	0.39	0.13, 1.13
Diary describes April to September	1.82	1.04, 3.20

themselves as Black, only White vs non-White children are contrasted in the models.

Analyses controlled for whether the child was randomly assigned or self-selected to his or her plan status (about equal numbers of diaries are from each group), whether the diary describes months from fall and winter (October to March) or from spring and summer (April to September), and which wave of data collection (first, second, or third) the diary is from. The self-select and random assignment groups were quite similar to each other in age, sex, ethnic composition, and rates of outpatient visits.

Results

Odds ratios from logistic regression models are shown in Tables 2 and 3. Table 2 presents the simplest model of the determinants of checkup and acute care visits. Initial tests showed no significant differences in use between the self-select and random assignment groups within each plan status, as might be expected since participation rates were similar. Because the use of care within the HMO did not differ between those who self-selected the HMO and those who were assigned to the HMO, a single indicator was used for the two HMO groups. Similarly, there were no significant differences between the two fee-for-service groups, which were also combined into a single variable. Table 2 shows that children enrolled in an HMO have a lower probability of an acute care visit. Although the coefficient on HMO enrollment just fails to meet the standard 5% test for statistical significance ($P = .056$), it is large enough to indicate that HMO enrollment triggers a real and important reduction in acute care visits. (In fact, the coefficient on HMO enrollment for acute care visits was negative and significant [$P = .020$] before we corrected the regression standard errors for covariance between repeated observations from the same child and from the same household. With this covariance correction, the coefficient estimate did not change but the estimated standard error became larger; consequently, the statistical significance just dipped below the 5% threshold [$P = .056$].) The predicted rate of acute care visits for plan children was only 14% while for fee-for-service children it was 23% (controlling for all other factors in the model). In contrast, on checkup visits, plan members and fee-for-service children were indistinguishable. Although possible reasons for these differences are discussed in detail in the Discussion section below, three obvious possibilities are noted here: (1) the HMO may provide better, more complete care at the time of the checkup, so fewer acute care visits are necessary; (2) the HMO may reduce unnecessary use among basically healthy children but may serve children with serious or frequent health problems at an

appropriately higher level; or (3) the HMO may respond to the incentives inherent in any capitation scheme and may underprovide needed services (e.g., by making it difficult to come in for acute care). This third explanation is not supported by the data in Table 2, however. If the HMO were withholding services, presumably the effect should also appear in rates of checkup visits, which it does not.

Child age has the expected effect on medical visits. The probability of any type of visit falls at a decreasing rate with age, bottoming out around age 10. Although boys typically are frailer than girls, sex is not a significant predictor of either acute or checkup visits when prior health status and age are controlled.

Children's prior health problems have different effects on acute care and checkup visits. A child with a major disabling condition (blindness, diabetes, cerebral palsy, mental retardation, cancer, missing limbs) was significantly more likely than a nondisabled child to visit a health provider for routine care (probability of a checkup = 41%), while a child with an allergy (eczema, asthma, hay fever, other skin and respiratory allergies) or "other" (nondisabling) condition had an above-average likelihood of an acute care visit.

Thirty-one percent of Whites but only 19% of non-Whites had a recent checkup visit. Although this variable is significant at only the 10% level, in the model reported here it had a significance level of .046 before correction for correlated observations.

The final variables that were considered are aspects of the survey administration: method of assignment and timing of the diary. The random assignment groups did not differ significantly from the self-selected groups in terms of use. The season of the year, however, did affect use. This site is in Florida, where the summer months bring significantly more acute care problems, presumably for ailments associated with exposure to sun and humidity and with moving between air conditioning and extreme heat. The coefficients on wave 2 and wave 3 show respondents reporting fewer acute care visits in later waves of the survey, independently of the season. This pattern, which cannot be readily explained, is consistent with the usage patterns observed in the claims data.

Table 2 indicates that the structure or practices of the HMO led to fewer acute care visits among enrolled children. Several hypotheses were tested that might explain this effect. The first was that the HMO might succeed in reducing care among children with few needs but might still see children with chronic problems at the same rate as under fee-for-service care. The fourth column in Table 2 supports this theory. The decline in acute care visits is concentrated among children with no health problems identified at the start of the experiment; their probability of an acute care visit in the 2-month period covered by a diary is only 11.5%, compared with a 16.7% probability for equally healthy children in the fee-for-service system. Children with one or more problems at the outset of the study had equal acute care visit probabilities in the two systems. As the third column shows, the likelihood of a checkup visit was not affected by plan enrollment for either group.

The hypothesis that physicians might provide more comprehensive care during visits to the HMO was tested using data on the content of acute and well care visits (e.g., whether the child received a urine test, throat culture, etc.). However, t tests revealed no significant differences between visit content in the HMO and the fee-for-service systems. Although children in the plan were somewhat more likely to have a urine test during a preventive visit ($P = .07$), they were somewhat less likely to receive a throat culture during an acute care visit ($P = .09$). Five other comparisons showed no significant differences.

Finally, the study sought to determine if the HMO selectively reduced emergency room visits relative to fee-for-service use. Overall, 2.4% of children used the emergency room for a checkup in a 2-month period and 4.8% visited it for an acute problem. Viewed differently, nearly one quarter of all acute visits and 9% of all checkup visits occurred in the emergency room. To determine whether, among those who used medical services, HMO enrollees were less likely to use the emergency room, the model made the probability of any visit to the emergency room conditional on the child having had at least one checkup or acute visit. As Table 3 shows, there are no significant differences between HMO and fee-for-service enrollees in their use of the emergency room. More elaborate models, examining acute and checkup emergency room visits separately, also failed to reveal any significant determinants of use.

Discussion

This paper has shown that an HMO reduced acute care visits for children on Medicaid but did not reduce emergency room use. The deterrent effect of HMO membership on acute care visits is not found across the board for all children. On the contrary, it is concentrated in a particular group: children with no health problems at the start of the experiment. Thus, the HMO appears to be targeting its services to children with the greatest health care needs rather than curtailing services across the board.

The question remains: Why should healthy HMO plan members have fewer acute visits than fee-for-service children do? Earlier we suggested three possible reasons: the plan provides more complete care during each preventive visit, it reduces necessary acute care, or it reduces unnecessary visits. Data on the content of well care visits do not offer any support for the first hypothesis. Nor do they support the second explanation: that the HMO is deliberately making care inaccessible to patients. If this were the case, presumably we would observe a negative effect of plan enrollment on checkup visits. However, the reduction in visits is limited to acute care visits by the most healthy children, which suggests that the HMO is able to "rationalize" its delivery of services rather than to merely ration services across the board. The assignment of a case manager to the HMO patients may have helped them receive advice over the telephone without making a visit. Since we have no data on telephone consultations, we cannot confirm this hypothesis. In contrast to the findings in Ware et al.,[13] patients with preexisting health conditions apparently received as much care in the HMO as they did in the fee-for-service system.

Although visits to the emergency room accounted for nearly one quarter of all the Medicaid children's acute care visits, the HMO did not selectively reduce emergency room use. In contrast to most previous studies, we found that the proportion of all HMO pediatric visits that occurred in the emergency room did not differ significantly from the proportion for fee-for-service patients. This may be because the HMO was sponsored by and located in the hospital with a large emergency department serving Medicaid patients. Thus, as was the case in Hurley et al.,[9] this plan may have had little incentive to divert patients from emergency room use.

The finding that the HMO reduced overall use by targeting health care services to those with the greatest health needs is encouraging news for advocates of Medicaid HMOs since it suggests that, in this experiment, the HMO may have

reduced unnecessary use without reducing care for children who need it. However, we must conclude on a cautious note. First, our results are based on practice at a single HMO. Second, while we have no evidence that the HMO was not providing needed services, neither can we claim that the HMO was remedying all deficits in care in a population vulnerable to inadequate care. □

The Role of State Health Departments in Formulating Policy: A Survey on the Case of AIDS

Leonard Robins, PhD, and Charles Backstrom, PhD

ABSTRACT

Objectives. Public health departments have been criticized for not being on the cutting edge of health policy formation in the United States and, in particular, for being ineffective in dealing with acquired immunodeficiency syndrome (AIDS). This study examines the attitudes and influence of public health officials on this problem.

Methods. A survey of state health department officials was supplemented by surveys of state legislature health committee chairs and hospital association directors, as well as by interviews with key AIDS policymakers and observers in six states.

Results. Both in their own eyes and in the eyes of legislative leaders and hospital association officials, public health officials were considered to be the principal initiators of public policy on AIDS.

Conclusions. Contrary to the Institute of Medicine's 1988 report, state health departments are leaders in the fight against AIDS at the state level. Moreover, we argue that public health departments should be judged on how effectively they perform functions for which they have primary legal responsibilities, not for other roles for which they have been given neither responsibility nor resources. (*Am J Public Health.* 1994;84: 905–909)

Introduction

In 1986 the Institute of Medicine established a Committee on the Future of Public Health to address a growing perception that the nation has "allowed the system of public health activities to fall into disarray."[1] After 2 years of study, the committee issued its report and concluded that "unfortunately, the findings of this committee confirm the concerns that led to the study."[1]

The committee report chose acquired immunodeficiency syndrome (AIDS) as an example of how poorly the public health system works. It emphasized the danger of public health officials having overly broad statutory power for imposing quarantine and implied that health agencies overemphasize surveillance at the expense of education. Finally, it asserted that health agencies have not supplied leadership in dealing with this new disease.[1]

The report gave several reasons for the general inadequacy of public health departments. Among the most important was its belief that public health officials were both naive about and contemptuous of the political process and hence lacking in political power.[1]

The purpose of this article is to examine these conclusions. But instead of focusing on the influence of public health professionals on the overall health care system of the United States, we ask a different question: How well are these professionals performing the classic public health functions that are still within their jurisdiction? We propose to determine this by emphasizing their role in the fight against AIDS—the greatest communicable disease challenge of our time and an issue that obviously offers an important role for public health agencies to play.

Methods

As part of an ongoing study of AIDS politics,[2] in the spring and fall of 1989, questionnaires concerning their state's policies on AIDS were sent to the nation's 50 state health departments, the 76 areawide hospital associations in the United States, and the chairs of all state House and Senate health committees. Those not responding within 3 weeks were sent a follow-up letter with another questionnaire. Ultimately, usable responses were received from 42 (84%) of the state health departments; 51 of the 76 (67%) state and regional hospital associations representing 39 (78%) of the states; and 68 legislative committees in 43 (86%) of the states. A number of the questions were common to all sets of respondents; other questions were geared to the special concerns of each category of respondents. Although the response rate was gratifyingly high, the total number of responses was inevitably relatively small. Because the universe of states was surveyed, no tests of statistical significance were used.

In addition to the surveys, field interviews were conducted with AIDS policymakers in six states—Arizona, California, Georgia, Illinois, New York, and Minnesota—in the fall and winter of 1989 to 1990.

This paper mainly reports the results from the state health departments survey, supplemented by selected findings from the other surveys and by occasional insights from the interviews.

Results

The Statutory Authority of Public Health Agencies

The Institute of Medicine's committee report asserted that "the statutory base of public health is poorly suited to dealing with AIDS." In particular, the committee was concerned about overly

TABLE 1—Priorities Given Various AIDS Efforts by State Health Departments (n = 40)

	Priority, %			
	Highest	High	Low	Should Not Do
Getting high-risk persons to change sexual behavior	70.0	27.5	2.5	0.0
Reaching minorities on AIDS prevention	52.5	42.5	5.0	0.0
Getting high-risk persons to test for HIV	43.9	51.2	4.9	0.0
Informing public about how AIDS is spread	34.1	56.1	9.8	0.0
Knowing extent of AIDS problem	26.8	73.2	0.0	0.0
Providing sufficient drug rehabilitation	32.5	47.5	20.0	0.0
Restricting persons with HIV from spreading it	24.3	51.4	13.5	10.8
Getting heterosexuals to practice safe sex	14.6	65.9	17.1	2.4

restrictive powers, including full isolation and quarantine, that had earlier been given to health departments.[1]

The relevant issue is whether state health departments endorse a policy of quarantining persons who have AIDS or who test positive for human immunodeficiency virus (HIV), or if they instead support a less restrictive policy. One alternative would be reliance on civil commitment procedures, to be used if a person who is HIV positive persists in behavior that endangers others even after being warned to cease. This is similar to the manner in which someone who is mentally ill and thought to need control is handled. Unlike quarantine, civil commitment is hedged with due process protections. Another option is using existing criminal statutes, under which a charge of assault could be brought against someone who is positive for HIV and who wantonly or carelessly infects others.

Respondents to our survey were asked whether their present state policy included quarantine, especially for AIDS; civil commitment authority; and/or the criminalization of risky behavior. They were also asked whether the health department favored such policies. In only one instance was quarantine for AIDS the theoretically official policy of the state, and in only that instance was quarantine favored. Thus, it is clear that quarantine is overwhelmingly opposed by state health officials and that, whether taking the lead or acting in alliance with others, they have successfully prevented it from becoming policy.

As for civil commitment, just over half of all respondents said they favored it, just over one quarter opposed it, and 43% said their states actually had such a policy. On the other hand, 38% of the states had criminal liability as their policy, which was favored by only one third of the health departments and opposed by the same proportion, with the rest uncertain or not responding.

In Minnesota,[3] interviews with health and legal officials dealing with AIDS revealed that state health officers were fully aware of the danger of untrammeled governmental powers. General quarantine statutes from the earliest days of statehood gave unrestricted power to the chief state health officer to isolate anyone with a serious communicable disease who appeared to be a threat to the public health. However, the state health department actually feared that the use of this statute—which contained no due process provisions such as notice and hearing—against AIDS would open them to justifiable complaint. As a result, they sought and obtained from the legislature a modification to make their powers conform to modern practice in civil commitment of the mentally ill. They did not want the quarantine statute repealed, however, because it provided them with a cover for opposing other restrictive laws about AIDS that might well have been passed. In fact, as evidence that the health department was actively protecting the larger public, they pointed to two, but only two, instances (a female and a male prostitute who were infected) in which they used the authority to restrain persons who did not respond to orders to desist.

It would appear that the state health officers are heeding the committee report's warning that public health statutes give state health departments overly broad and restrictive powers. Not only do they not want additional draconian powers, but they in fact oppose use of "solutions" such as quarantine. Contrary to the common assumption that any bureaucracy always desires more power, they show a sophisticated understanding of what constitutes appropriate legal powers against AIDS.

Data Gathering and Analysis

The Institute of Medicine's report noted that "some health agencies are accused of overemphasizing surveillance at the expense of preventive efforts such as education."[1] Given the use of the word *some*, this is undoubtedly true. Surveillance is the traditional core of classic public health, and the inevitable interface of AIDS education with sex and drug use ensures that such education will be controversial. Nonetheless, as Table 1 shows, in terms of efforts to deal with the disease, state health departments are far from being totally preoccupied by surveillance issues.

Although in no state did public health officials assign a low priority to knowing the extent of AIDS in their state, five other AIDS efforts were considered by a greater proportion of state health departments to have highest priority. Surveillance, however, was ranked as highest priority by more health officials than were two other listed efforts. Thus, while all state health departments consider surveillance important, many are equally or more strongly committed to more activist aspects of AIDS control.

Influence on Policy

The institute report makes the following charge:

> Among the many groups and individuals, public and private, engaged in fighting AIDS, health agencies have not taken a clear initiative in supplying leadership, and the public is unclear about what level of government it should look to for guidance or what it can appropriately and realistically expect any particular health agency to do.[1]

It is indeed undoubtedly true that the public is unsure of which level of government is responsible for various activities. Alas, that is true of almost all public policy problems, save perhaps for national defense at one extreme and fire protection at the other. The only concern of the public is whether anyone is doing the job. In this case, the issue is whether state health departments have a leading role in AIDS policy development.

As evidence that health departments are often not critical players in the

Note. Percentages of a single rating group may not total 100.0 across because the answers of those who volunteered "Don't know" are not tabulated; percentages may exceed or not equal 100.0 because of rounding.

formulation of AIDS policies, the report quotes a legislative staffer:

> The legislature has been the leader. . . . Such leadership should have come from the Department of Health Services. The state health director knows less than I do about what's happening in the state![1]

Our study finds otherwise.

Table 2 presents the relative assessment by state health department heads, legislative health committee chairs, and hospital association directors of the influence of various actors on state AIDS policy. Potential actors are grouped into the following categories: health department heads, elected officials, health providers, affected groups, and ideological groups.

Perhaps not surprisingly, health departments rated themselves as being the most influential actors on AIDS policymaking in their states. Sixty percent felt they were very influential and 38% thought they were somewhat influential in setting AIDS policy; only one respondent believed they had little influence and not a single one asserted they had no influence.

Strong confirmation of the influential role that health departments play in AIDS policymaking is provided by the other groups surveyed. Legislative health committee chairs and hospital association professionals ranked the health departments clearly higher in influence than they ranked any other actor.

The next most influential AIDS policymakers were seen to be legislative leaders. Well over half (57%) of the health departments perceived legislative leaders as very influential and more than one third (36%) said somewhat influential. This assessment was seconded by the legislative chairs and the hospital association professionals.

Although somewhat less important, the governor was the only other actor believed to have substantial influence on AIDS policymaking. Forty-three percent of health departments rated their governor as being very influential and 41% said somewhat influential. Hospital associations ranked the governor similarly. Legislative respondents, on the other hand, ranked the governor substantially lower.

At a distinctly lower level of influence stand health provider associations. Only about a quarter of the health departments rated their state medical associations as highly influential, but more than three in five classified them as

TABLE 3—Perceived Importance of Various Functions of State Health Department Regarding AIDS Policy (n = 42)

Functions	Highest Importance, %	High Importance, %	Important, %	Not Important, %
Devising appropriate statewide policies	54.8	42.9	2.4	0.0
Making the public more aware of AIDS	45.2	38.1	16.7	0.0

TABLE 4—Respondents' Ratings of the Effectiveness of Possible "Liberal" and "Conservative" Strategies for Adopting AIDS Policies (n = 39)

	Effectiveness of Strategy, %			
	Good	Uncertain	Poor	Edge: Good-Poor
"Liberal" strategies				
Emphasize human interest; people suffer	70.0	22.5	7.5	62.5
Argue the effectiveness of liberal measures	64.1	28.2	7.7	56.4
Stress community values; helping others	43.6	41.0	15.4	28.2
Urge keeping AIDS out of electoral politics	38.5	48.7	12.8	25.7
Encourage threatened groups to work together	30.8	43.6	25.6	5.2
Make stand on protection of civil liberties	33.3	30.8	35.9	−2.6
"Conservative" strategies				
Point out the need to protect innocent people	87.2	10.3	2.6	70.7
Make stand on the duty to protect public	64.1	30.8	5.1	59.0
Dramatize the threat to the general public	61.5	33.3	5.1	56.4
Emphasize how those at risk differ from majority	43.6	33.3	23.1	20.5
Encourage greater cohesion among conservatives	33.2	56.4	10.3	22.9
Argue that AIDS is a valid election issue	17.9	59.0	23.1	−5.2

having some influence. Legislative chairs pegged the medical associations somewhat higher, but hospital association directors ranked them far lower in influence. As for hospital associations, 14% of the health departments believed them to be very influential in AIDS policymaking, but 64% said they had only some influence. Legislative chairs ranked them higher, but only 25% of these respondents classified hospital associations as very influential, and slightly fewer of the hospital associations (23%) ranked themselves as being very influential.

Weakest among provider groups is the insurance industry, which only 7% of the health departments rated as very influential. Legislative chairs and hospital associations ranked them somewhat higher but still below the other providers.

Affected groups such as persons living with AIDS and organized gays were seen by fewer than 1 in 10 health departments as being very influential. At an even lower level of influence were ideological organizations and church leaders. Only conservative organizations were seen as highly influential by any rating group, being so classified by 14% of the health departments.

Political scientists have long debated the usefulness of reputation as a surrogate measure for actual public policy influence since there may well be a low correlation between who is thought to have influence and who has it in reality. This doubt is especially persuasive when those whose opinions are asked are not experts on the subject and are not themselves involved in decision making on the matter at hand. In this case, however, those responding were themselves specialized elites working in the same subject matter area: AIDS.

Understanding the Political Process

The Institute of Medicine report was also very critical of public health officials for their lack of political skill and understanding:

> Too frequently during its investigations, the committee heard legislators and members of the general public castigate public health professionals as paper-shufflers, out of touch with reality, and caught up in red tape.... Yet many public health professionals who talked with us seemed to regard politics as a contaminant of ideally rational decision-making processes rather than as an essential element of democratic governance. We saw much evidence of isolation and little evidence of constituency-building, citizen participation, or continuing (as opposed to crisis-driven) communication with elected officials or with the community at large.[1]

Although it is undoubtedly true that some public health officials lack political sophistication, our study results contradict the view that public health officials are generally politically inept and ignorant, at least with regard to AIDS. Two questions from our survey included political content most pertinent to this subject.

First, to test the view that state health departments are preoccupied with their internal procedures, respondents were asked how important they regarded each of various aspects of their job as it concerned AIDS (Table 3). Developing innovations in the agency's AIDS program—an inward-focused activity—was found to be the least important function in the eyes of the respondents. Although all respondents believed that internal innovations are important, fewer than one third (29%) considered it the highest priority, the lowest among the six categories suggested.

It should be acknowledged that higher importance given by state health departments to external rather than to internal functions does not automatically mean that these departments are doing a good job of constituency building or fostering citizen participation. It does strongly suggest, however, that they are not preoccupied with paperwork and that communication with elected officials is more than episodic. Evidence earlier presented ranking their influence on AIDS policy reinforces this view.

Second, to investigate the charge that public health professionals are ignorant of and have contempt for the political

process, respondents were asked to rate the effectiveness of a wide array of various "liberal" and "conservative" strategies for influencing AIDS policy. We then computed the "edge" by which respondents label a strategy as good over those who think it is poor (Table 4). Least support among liberal strategies (receiving 33% and the only negative edge) was given to stressing civil liberties as an effective approach. Conversely, an overwhelming majority (70% with a 63% edge) considered emphasizing human suffering as a good strategy from the liberal perspective. A massive majority (87% with a 71% edge) endorsed emphasizing the need to protect innocent victims as a good conservative strategy. On balance, a small group (23% with a −5% edge) thought that arguing that AIDS is a valid election issue would be a poor strategy.

To us as political scientists, these judgments show political sagacity. While the analysis of these responses as indicators of political sophistication must inevitably be subjective, interviews with non-health policy actors and observers of the legislative process in the six states visited generally show agreement with the health departments' assessments.

Discussion

Our study of AIDS policymaking found that, in dealing with AIDS, public health departments are very influential. Moreover, both our surveys and our interviews convinced us that public health professionals promoted their ideas with a clear understanding of their political environments and the strategies appropriate in them. These findings dramatically differ from the Institute of Medicine's indictment of public health professionals, in which public health was characterized as being in disarray and politically amateurish.

How do we account for these different perspectives? One explanation may be that the negative view expressed in the institute's report is generally correct and that our findings refute its assertions only when applied to AIDS. But the context in which public health operates has also changed with the challenge of AIDS. A massive communicable disease threat at a time when antibiotics had seemingly downgraded the necessity for classic public health presented the opportunity for public health agencies once again to move to center stage instead of being relegated to unglamorous activities like restaurant inspection.

More fundamentally, we suggest that our conclusions arise from different evaluation criteria. The Institute of Medicine spent a good deal of time noting that many important health issues are not under the jurisdiction of public health departments. This, however, is a strange criterion. It is perfectly appropriate to recommend the consolidation of health functions under a superagency, but it is wrong to use the failure of this to occur as evidence of the inadequacies of public health professionals. Why should we be surprised that environmentalists or mental health specialists want their own agencies, or that they have been able to succeed in turning those agencies into separate departments, since public health professionals themselves do not like to be a division of a superagency?

Similarly, the criticism that public health agencies have not acted to institute major reforms of the health delivery system is unfair. Unfortunately, the US government has not yet enacted national health insurance, but this requires a political decision at a more fundamental level than bureaucrats can provide.

Thus, we show that these maligned public health agencies reacted with professional competence and political skill (two not unrelated aspects) to deal with the threat of AIDS. Perhaps public health professionals are rarely thought about in routine times, but they are nonetheless quite competent when a public health emergency arises in which they are needed. Their apparent decline is true at most only in a relative sense. □

The Use of Nonoxynol-9 for Protection against Cervical Gonorrhea

Sharon S. Weir, MA, MPH, Paul J. Feldblum, PhD, Leopold Zekeng, PhD, and Ronald E. Roddy, PA-C, MPH

ABSTRACT

Objectives. Although condoms are the best defense against sexually transmitted disease, little is known about the effectiveness of female-controlled methods containing nonoxynol-9 as backup protection when condoms are not being used.

Methods. To assess the extent to which nonoxynol-9 protects women against gonorrhea, a cohort of 303 female sex workers (prostitutes) in Yaounde, Cameroon, were asked to use condoms and suppositories containing nonoxynol-9 at every sexual encounter and to record daily sexual activity and use of condoms and suppositories on coital logs that were reviewed monthly. Evidence of gonorrheal infection was based on a positive gonorrhea culture. Stratified analysis and proportional hazards regression were used to estimate rate ratios.

Results. Forty-one women enrolled in the study were excluded from the current analysis. The estimated incidence of gonorrhea was 6.2 infections per 100 person-months of observation. Incidence rate ratios estimated from proportional hazards regression models controlling for condom use showed that using nonoxynol-9 during acts not protected by condoms reduced the risk of infection.

Conclusions. Although the protective effect of condoms against sexually transmitted disease is greater than that afforded by nonoxynol-9, using nonoxynol-9 when condoms are not used is a far better strategy in gonorrhea prevention than using no method at all. (*Am J Public Health.* 1994;84:910–914)

Introduction

When used properly, condoms are effective in preventing most sexually transmitted diseases, including cervical gonorrhea.[1-5] However, the underuse of condoms among people at high risk for sexually transmitted diseases suggests that there is an urgent need for alternative methods.[3,6,7] Clinical and epidemiological studies indicate that the spermicidal compound nonoxynol-9 can be effective in vitro[8,9] and in vivo[10-15] in preventing gonorrheal infection. Spermicides have some desirable properties for women not shared by condoms. Most notable, a woman can insert a spermicidal compound ahead of time, without the need for her partner's direct involvement or cooperation.

Between 1989 and 1990, a cohort study of female sex workers (prostitutes) in Yaounde, Cameroon, was conducted to assess the protective effect of nonoxynol-9 against human immunodeficiency virus (HIV) infection. Study results regarding the association between use of this compound and HIV infection have been published elsewhere.[16] This paper presents a further analysis of those cohort data to assess the extent to which nonoxynol-9 afforded protection against cervical gonorrhea.

Methods

Public health authorities enrolled 303 Cameroonian female sex workers in the study. Eligibility criteria included (1) age of at least 18 years; (2) no pregnancy during the previous 42 days (by self-report); (3) no history of adverse reaction to a spermicidal product; (4) negative enzyme-linked immunosorbent assay (ELISA) HIV antibody test; and (5) willingness to use the study products, maintain a coital log (a calendar on which coitus, condom use, and spermicide use could be marked daily), and return monthly for 1 year for follow-up visits.

At admission, following an explanation of the study and their written informed consent, participants were administered a brief questionnaire to obtain information on their sociodemographic characteristics, sexually transmitted disease symptoms, and sexual practices. The women were advised to use condoms and vaginal suppositories containing nonoxynol-9 at every intercourse, and they were instructed in proper use of these products. Plain lubricated (nonspermicidal) latex condoms and vaginal suppositories containing 100 mg of nonoxynol-9 were provided at admission and were freely available throughout the study. (The other ingredients in the suppositories were polyethylene glycol, benzethonium chloride, citric acid, D&C red no. 21, D&C red no. 33, methylparaben, and water.) The women were instructed to return monthly, at which time they were interviewed about their sexual practices, use of medication, and sexually transmit-

ted disease symptoms during the past month; were given a pelvic examination with gonorrhea culture; and had their coital logs reviewed and tallied by project staff who did not know whether the women were infected with gonorrhea. (The coital logs contained a picture of a condom and a suppository for each act. The woman marked the method used, if any, with an X. The logs were completed each day.)

All participants were offered a small monetary incentive for transportation costs (equivalent to the cost of a shared taxi ride) at each visit; free condoms and vaginal nonoxynol-9 suppositories throughout the study; free physical examinations, diagnostic tests, and appropriate sexually transmitted disease therapy for any infections diagnosed during the study; and pre- and posttest counseling by study staff. The protocol was approved by the Cameroon National AIDS Control Service and the Family Health International Protection of Human Subjects Committee.

Classification of Exposure

The classification of exposure to nonoxynol-9 for each participant was based on coital log data, taking into account condom use. First, the cumulative number of coital acts for each participant was determined by adding together the number of acts reported on monthly coital logs until one of the following occurred: incident gonorrheal infection, missing coital log data or missing gonorrhea test result data, other loss to follow-up, or end of the 12-month study. Next, each coital act was classified into one of four categories representing the four possible combinations of condom and nonoxynol-9 suppository use (i.e., concurrent condom and suppository use; only suppository use; only condom use; and neither condom nor suppository use). In initial life table and proportional hazards regression analyses, acts protected by condoms alone and acts protected by condoms and nonoxynol-9 together were combined into the category of acts protected by condoms because the initial study question was whether nonoxynol-9 afforded protection during acts when condoms were *not* used. In subsequent exploratory analyses, all four categories were used.

Classification of Disease

Evidence of gonorrheal infection was based on a positive gonorrhea culture (typical colony morphology, oxidase positive, and gram stain positive). Swabs were taken from the endocervix, plated directly onto modified Thayer-Martin media, and incubated under carbon dioxide conditions. Plates were read at 24 hours and, if no growth was apparent, at 48 hours.

TABLE 1—Mean Percentage of Coital Acts Protected by Condoms and Nonoxynol-9 Suppositories Together, Condoms Only, Nonoxynol-9 Suppositories Only, or Neither Method

	Mean % of Acts Protected	SD	Range, %
Both methods	40.5	22.8	0–100
Condoms only	22.2	15.5	0–98
Nonoxynol-9 suppositories only	24.9	16.2	0–82
Neither method	12.4	13.5	0–83

Statistical Methods

Crude assessments of the protective effect of condom use and of nonoxynol-9 use during acts not protected by condoms were made by graphical representation of the life table curves of time until incident gonorrhea for varying levels of use. Effect modification was assessed through stratified analysis to identify variables whose effect, when combined with the level of nonoxynol-9 use, was greater than would be expected if the effects were independent and simply additive. Potential confounders of the exposure-disease relationship identified through stratified analysis were included in initial proportional hazards regression models and then dropped, based on the extent to which their exclusion changed the estimated rate ratios.[17] The rate ratios for the exposure variables were estimated by SAS proportional hazards regression software.[18]

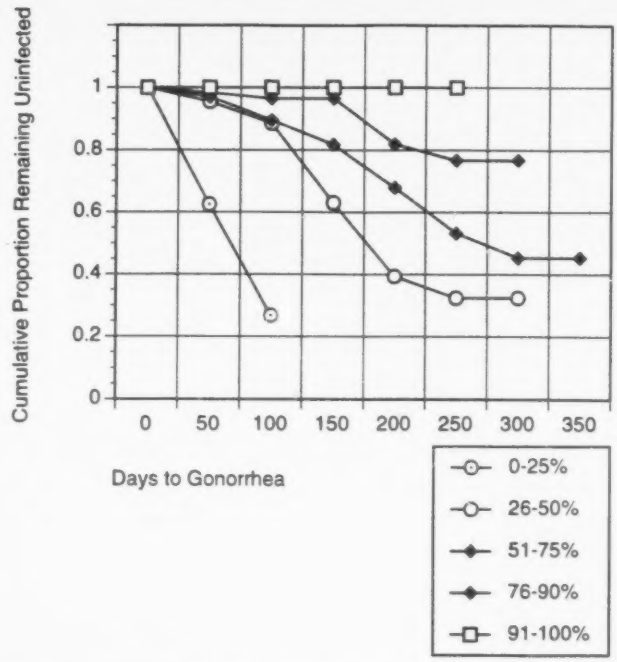
Results

Because the primary research question for the cohort study was the protective effect of nonoxynol-9 against HIV, 30 women were excluded from the cohort owing to positive ELISA tests and confirmatory Western blot, either at admission or during the first 3 months. Western blot results were considered positive if they showed at least two envelope bands (World Health Organization criteria[19]). Of the remaining 273 women, seven (2.6%) with positive cultures for endocervical gonorrhea at admission were excluded from the analysis, as was one woman with missing gonorrhea test data at baseline but confirmed evidence of gonorrhea at the time of the first follow-up. Three women did not report any sexual partners during the brief period they were in the study before dropping out; they were also excluded. Included in the analysis, then, were 241 women with negative gonorrhea culture tests at admission and 21 additional women whose gonorrhea culture results were missing at admission but who had a negative culture at the next follow-up. This latter group was treated as if their date of admission was the first follow-up visit.

At admission, approximately a third of the women were less than age 25; 37% were 25 to 29; and the remainder were 30 to 45. About 45% had completed schooling in addition to primary school. Fewer than 10% had ever married. The women were sexually active; over 40% had more than 15 sexual partners per month. Fewer than 15% reported using a contraceptive method at admission.

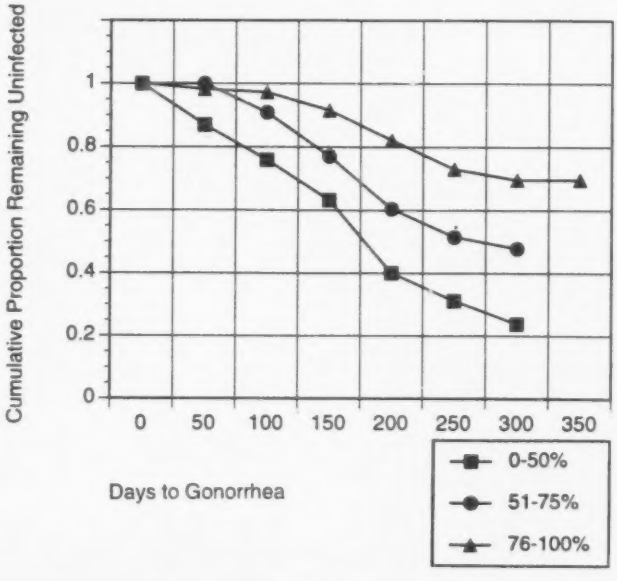
During follow-up, compliance in using condoms and nonoxynol-9 was quite high (Table 1): the mean percentage of coital acts protected by using both methods together was 40%; by using condoms alone, 22%; by using nonoxynol-9 alone, 25%; and by using neither, only 12%. Eight percent reported using both condoms and nonoxynol-9 for more than 75% of all acts; 22% used either condoms, nonoxynol-9, or a combination for all acts; and fewer than 2% used no protection at all for more than 50% of all acts.

Ninety-five women contracted gonorrhea during the almost 1500 person-months of observation for an estimated incidence of 6.2 gonorrhea infections per 100 person-months of observation. Of the remaining 167 women, 94 were censored because of study discontinuation, 23 were censored because of incomplete data, and 50 were censored at the end of the study period. Initial life tables demonstrated the protective effect against gonorrhea of condoms (Figure 1; $P < .0001$ log-rank test) and of nonoxynol-9 during acts not protected by condoms (Figure 2; $P < .0001$ log-rank test). The incidence of gonorrhea by nonoxynol-9 level among high, medium, and low condom users (Table 2) and rate ratios show that the rate of infection fell as condom use increased and, within levels of condom



Note. Ranges represent levels of the variable (number of coital acts with condom use divided by the total number of coital acts reported).

FIGURE 1—Gonorrhea life table rates, by condom use.



Note. Ranges represent levels of the variable (number of coital acts with nonoxynol-9 use divided by the number of coital acts without condom use).

FIGURE 2—Gonorrhea life table rates, by nonoxynol-9 use during coital acts not protected by condoms.

use, as the level of nonoxynol-9 use increased.

Among the variables considered as potential effect modifiers or confounders during stratified analysis or initial proportional hazards regression (i.e., age, educational attainment, oral contraceptive use, previous treatment for sexually transmitted disease, and presence of a dependent child), none clearly modified the dose–response protective effect of nonoxynol-9 described in Table 2. At levels of use higher than 50%, the protective effect of nonoxynol-9 was lower for a subgroup of young women (younger than age 30) who had completed secondary school than it was for other women; however, this was not evident at lower levels of nonoxynol-9 use. Because there was not a consistent difference in effect at all levels of nonoxynol-9 use and because the joint effect of being a young educated woman and of nonoxynol-9 level was less than multiplicative, a variable indicating membership in this subgroup was not included in the model.

The rate ratios and 95% confidence intervals (Table 3) were estimated by a proportional hazards model that included three levels of condom use (with less than 50% use being the reference group) and three levels of nonoxynol-9 use (with less than 25% use being the reference group). After controlling for condom use, using nonoxynol-9 during acts not protected by condoms provided increasing protection with increasing level of suppository use. Women using nonoxynol-9 for more than 75% of acts not protected by condoms had a rate of infection that was 14% that of women who used the compound for fewer than 25% of such acts. Even using nonoxynol-9 for only 26% to 50% of acts not protected by condoms reduced the rate of infection by half.

Acts protected by condoms in the life table and proportional hazards analyses reported above included acts protected by both a condom and a nonoxynol-9 suppository as well as acts protected only by a condom. The strong protective effect of nonoxynol-9 that was demonstrated in these data, however, raised the issue of the relative protective effects of nonoxynol-9 suppositories, condoms, and the concurrent use of both methods. Results from a proportional hazards model that included four continuous variables—the proportion of acts protected by condoms alone; the proportion protected by nonoxynol-9 alone; the proportion protected by both methods; and the number of sexual acts during the period—showed no

significant difference between the protective effect of using condoms alone, of using nonoxynol-9 alone, or of using both together. For every 1% increase in the use of condoms alone, nonoxynol-9 alone, or both together, the risk of gonorrhea was reduced. The estimated rate ratios (and 95% confidence intervals) were 0.956 (0.942, 0.971) for both methods together; 0.963 (0.946, 0.981) for condoms alone; and 0.960 (0.943, 0.976) for nonoxynol-9 suppositories alone. The protective effect of each method was also apparent in other exploratory proportional hazard models that used the number rather than the proportion of acts protected by each method.

The single best predictor in these data of the rate of gonorrhea was the proportion of acts protected by neither nonoxynol-9 nor condoms. Rate ratios estimated by a proportional hazards model that included only the proportion of acts not protected by either method (Table 4) show that as the proportion of unprotected acts increased, the rate of infection increased sharply.

TABLE 2—Incidence Rates of Gonorrhea per 100 Person-Months and Rate Ratios (RRs), by Levels of Condom Use and Nonoxynol-9 Use

Level of Nonoxynol-9 Use	Level of Condom Use: ≤50%		51%–75%		>75%	
	Incidence	RR	Incidence	RR	Incidence	RR
<25%	39.6	1.00	12.9	1.00	10.4	1.00
26%–50%	20.3	0.51	12.1	0.94	4.5	0.43
51%–75%	10.6	0.27	6.6	0.51	1.8	0.17
>75%	7.4	0.19	3.5	0.27	1.2	0.12

Note. Level of condom use refers to the percentage of total coital acts in which a condom or both a condom and nonoxynol-9 was used. Level of nonoxynol-9 use refers to the percentage of the remaining acts that were not protected by a condom or by both a condom and nonoxynol-9 and in which only a nonoxynol-9 suppository was used.

TABLE 3—Rate Ratios for Gonorrhea Infection from Proportional Hazards Model of Nonoxynol-9 Use, with Condom Use Controlled

	Rate Ratio	95% Confidence Interval
Level of nonoxynol-9 use among acts not protected by condoms		
>75%	0.14	0.07, 0.29
51%–75%	0.23	0.12, 0.46
26%–50%	0.48	0.23, 0.97
0%–25%[a]	1.00	. . .
Level of condom use		
>90%	0.05	0.01, 0.39
76%–90%	0.20	0.10, 0.39
51%–75%	0.44	0.29, 0.69
0%–50%[a]	1.00	. . .

Discussion

This study confirms findings from other studies that have shown that condoms offer significant protection against gonorrhea. Given the risk of other sexually transmitted diseases, including HIV infection, women who have multiple sexual partners, such as the sex workers enrolled in this study, should consistently use condoms. However, in cases where condoms are not used owing to refusal by the male partner or to other reasons, this study demonstrates the substantial protection against gonorrhea afforded by nonoxynol-9 and provides evidence that use of the suppository alone is a reasonable strategy, especially when the alternative is a lack of protection by either method.

The level of protection provided by nonoxynol-9 in this study is similar to that reported in other studies. In fact, the rate ratios comparing gonorrheal infection among high and moderate nonoxynol-9 users with infection among less frequent users are quite similar. Niruthisard et al.[15] compared the incidence rates for chlamydial or gonococcal cervical infections among three categories of nonoxynol-9 users based on the percentage of coital acts in which nonoxynol-9 was used (76% to 100%, 51% to 75%, and 0% to 50%). They reported rate ratios of 0.4 and 0.7 for the high- and moderate-use groups, respectively, compared with the lowest-use group. Using similar categories (76% to 99% use, 51% to 75% use, and 0% to 50% use), Louv et al.[13] reported rate ratios of 0.3 and 0.5 for the high- and moderate-use groups, respectively. When the categories of Niruthisard et al. were applied to the data from Cameroon, the estimated rate ratios were similar: 0.4 for high users and 0.6 for moderate users compared with the lowest-use group.

Previous studies have not taken into account the extent to which women used condoms and nonoxynol-9 together or separately. This may have limited the ability of these studies to detect the dose–response protective effect of nonoxynol-9 evident in these data. This is because women who use nonoxynol-9 as a backup method when condoms are not used may have fewer completely unprotected acts (but lower absolute nonoxynol-9 use) than women who use condoms and nonoxynol-9 together most, but not all, of the time. In this study, the best indicator of risk of gonorrhea was the proportion of acts left unprotected by either method, not the absolute level of condom or nonoxynol-9 use.

TABLE 4—Rate Ratios for Gonorrhea Infection from Proportional Hazards Model of Proportion of Coital Acts Not Protected by Condoms or Nonoxynol-9

Proportion of Acts Unprotected	Rate Ratio	95% Confidence Interval
0–9%[a]	1.0	. . .
10–19%	2.6	1.5, 4.5
20–29%	4.5	2.5, 8.1
30–39%	9.0	4.6, 17.6
≥40%	31.0	13.3, 72.1

[a]Reference group.

There are several weaknesses of this study. The lack of randomization to condom or nonoxynol-9 use means that there may be unknown factors associated with risk of gonorrhea that differ substantially in their distribution between users of condoms and of nonoxynol-9. Perhaps young educated women who were high users of nonoxynol-9 were more likely to have partners with a higher prevalence of gonorrhea; perhaps women who used both methods at every intercourse, and were therefore more compliant, were more eager to reduce their risk of infection in other ways and avoided other unknown activities that increased the risk of infection.

In addition, the level of protection reported here for both condoms and nonoxynol-9 is likely to be underestimated in that the level of condom and nonoxynol-9 use among the reference groups was still significantly higher than zero. To the extent that condom and nonoxynol-9 use were overreported, which would not be surprising in spite of the admonitions given to record use of both methods accurately, the rate ratios would also be underestimated. The level of protection reported here is likely to be overestimated for the entire population of women from whom the cohort was obtained in that the women who volunteered for this study probably have higher levels of compliance with condom and nonoxynol-9 use than women who were not able to complete monthly coital logs and attend the clinic regularly for monthly checkups.

Results from the proportional hazard models exploring the relative protection afforded by nonoxynol-9 alone, condoms alone, and both methods together should be interpreted with caution. The estimated rate ratio for a 20% increase in the use of nonoxynol-9, for example, is 0.44, indicating that the risk of gonorrhea would be reduced by more than half. Even though there was no clear evidence of the risk of gonorrhea being nonlinear in the logit for the continuous variables, we are not willing to assume that an increase from 30% to 50% would have the same protective effect as an increase from 80% to 100%.

In conclusion, although the protective effect of condoms against sexually transmitted disease is greater than that afforded by nonoxynol-9, the protective benefit of nonoxynol-9 against gonorrhea is substantial. Using nonoxynol-9 when condoms are not used is a far preferable strategy in gonorrhea prevention than using no method at all. As Cates and Hinman argue in the case of HIV prevention,[20] controlling the gonorrhea epidemic will require different, mutually reinforcing approaches and the use of partially effective methods, which, if more acceptable to the target population, may ultimately have a greater effect on disease incidence than may more effective but less well accepted methods. □

Are Bisexually Identified Men in San Francisco a Common Vector for Spreading HIV Infection to Women?

Maria L. Ekstrand, PhD, Thomas J. Coates, PhD, Joseph R. Guydish, PhD, MPH, Walter W. Hauck, PhD, Linda Collette, MS, and Stephen B. Hulley, MD, MPH

ABSTRACT

Objectives. This article examines sexual risk taking among self-identified bisexual men in San Francisco and whether risk reduction has occurred, with respect to both homosexual and heterosexual behaviors, among human immunodeficiency virus (HIV) antibody–positive and HIV antibody–negative men. It also examines psychosocial correlates of unprotected anal and vaginal intercourse.

Methods. The participants were members of a population-based longitudinal cohort of 1034 single men aged 25 through 54 years recruited from the 19 census tracts in San Francisco that had the greatest prevalence of the acquired immunodeficiency syndrome in 1984. Of the total sample, 140 subjects initially identified themselves as bisexual; 85% of these men remained in the study.

Results. The participants reported dramatic reductions in sexual risk taking. Prevalences of unprotected anal sex with men were similar among HIV-positive bisexual men (89% in 1984–1985 and 18% in 1988–1989) and those who were HIV negative (65% and 20%). The prevalence of unprotected vaginal sex was much lower for HIV-positive men (16% in 1984–1985 and 2% in 1988–1989) than for HIV-negative men (35% and 20%). Unprotected intercourse was associated primarily with situational and interpersonal factors.

Conclusions. Striking reductions in risk behaviors were reported. This subgroup of single, bisexually identified men appears unlikely to be a common vector for spreading HIV infection to women. (*Am J Public Health.* 1994;84:915–919)

Introduction

This study was designed to examine the prevalence of and change in sexual behaviors among San Francisco men who identified themselves as bisexual. The US Department of Health and Human Services reported that as of October 1991, 10% (n = 625) of all heterosexually transmitted acquired immunodeficiency syndrome (AIDS) cases among women were reported to be due to sexual contact with a bisexual man.[1] It is important to learn more about both the prevalence and the patterns of sexual behaviors among bisexual men, as well as psychosocial correlates of unprotected sex, as a guide to developing appropriate AIDS prevention campaigns for this population.

A recent study that used national surveillance data on US men with AIDS found that at least 14% were behaviorally bisexual.[2] The results further showed that nearly one quarter of bisexual men with AIDS who died were married at the time. It is unclear to what extent female sex partners are aware of the behaviors of bisexual men, but data from the California Partners' Study[3] suggest that this awareness may vary depending on ethnicity. Among 52 female partners of human immunodeficiency virus (HIV) antibody-positive bisexual men, 80% of the White, 20% of the African-American, and 22% of the Latina women were aware that their male sex partners were bisexual. Although these studies suggest that women may indeed be at risk for HIV transmission from bisexual men, they provide no data on the sexual risk-taking behaviors of these men.

In a study of homosexually active British men,[4] 61% of the participants reported having engaged in some heterosexual behaviors during their lifetime. Although only 12% of the sample reported having had a female partner during the past year, 92% of these men stated that these were "penetrative partners" (i.e., partners with whom they had practiced anal or vaginal sex). In addition, condom use was poor among these men, with only 28% reporting consistent condom use during vaginal intercourse. These findings suggest that there may be differences in sexual risk taking among bisexual men depending on the gender of one's sex partner. However, they provide no information about behavior change or correlates of risk taking.

The San Francisco Men's Health Study consists of single men who at baseline had engaged in sex with men, women, or both in the past 2 years. An early study[5] of the participants found that 5% (n = 50) of the men were HIV positive and bisexual. These men reported having had sex with an average of 2.9 women during the 2 years before baseline. This finding led the authors to conclude that "a substantial potential clearly exists for epidemic spread of [HIV] infection to women in San Francisco."[5(p901)]

In our previous studies of behavior change in this sample, we found that gay men made unprecedented and lasting sexual-behavior changes.[6] No analysis has been conducted of bisexual behavior since the 1984 baseline visit.[5] Previous research[6–9] with this and other cohorts

identified several important correlates of unprotected anal intercourse among gay men. We are not aware of any previous studies of correlates of sexual risk taking among bisexual men.

This article focuses on sexual behavior and its psychosocial correlates among self-identified bisexual men in the San Francisco Men's Health Study. This analysis had four goals: (1) to examine the relationship between behavioral bisexuality and having a bisexual identity; (2) to determine whether risk reduction has occurred with respect to both homosexual and heterosexual activities within this population; (3) to examine the relationship between HIV antibody status and unprotected sexual intercourse among bisexual men; and (4) to determine whether there is an association between psychosocial variables and unprotected sexual intercourse with men and/or women in this population.

Methods

Subjects and Procedures

The San Francisco Men's Health Study is a prospective study of single men recruited by stratified two-stage probability sampling from the 6-km^2 area in San Francisco with the highest cumulative incidence of AIDS in 1984. The study sample and methods were described in detail previously.[10,11] All single men between the ages of 25 and 54 years who lived in one of the selected housing units were contacted by the survey workers and invited to participate in the study. Fifty-nine percent (n = 1034) of these men entered the study. Analyses of selected characteristics of the study subjects and those of comparable men in the same census districts showed the study sample to be representative of all contacted subjects with regard to demographic characteristics.[11] We have no data on whether study participants were representative of all contacted men in terms of their sexual behaviors or of bisexual men who are married or live in other parts of San Francisco.

The initial wave of data collection took place in July 1984 at the outpatient clinic of the Children's Hospital in San Francisco. The interviews lasted approximately 1 hour and focused on sexual behaviors, physical symptoms, other relevant health-related behaviors, and psychosocial variables. After the interview, a physical examination was performed by specially trained physician assistants. Follow-up assessments have taken place every 6 months. Psychosocial questionnaires were administered in 1985, 1987, and 1989.

Participants were given a list of different terms describing sexual orientation (i.e., gay, homosexual, bisexual, straight, heterosexual, and "other"). All participants who described themselves as bisexual in the first year of data collection (n = 140) were included in these analyses. Demographic subject characteristics obtained in 1984 showed that 85% of the bisexual men were White, 7% were Black, and 7% were Latino. The age range at entry into the study was 25 to 54 years, with a mean of 35 years. The majority of the participants (64%) had bachelor's degrees, and 56% of these had completed some postgraduate work. These rates were comparable to those obtained for the entire San Francisco Men's Health Study sample.[6]

Measures

Sexual behavior. Self-report data on high-risk sexual behavior were obtained every 6 months, starting in July 1984 and ending in June 1989. In the present analyses, we examined the number of male and female sex partners, unprotected anal and vaginal sex, and oral sex with men and women. The semiannual data from the first and last two waves were combined into two 12-month segments, labeled "year 1" and "year 5." Thus, an individual who had practiced a behavior in either or both of two consecutive 6-month waves would be coded as having practiced the behavior in that year.

Because these were secondary data analyses, the selection of measures of potential risk-behavior correlates was not theoretically based. Rather, our decision to include these measures was primarily empirically based. Virtually all of these measures were previously shown to be associated with risk-taking behaviors in cohorts of gay and bisexual men.

Age. Age was entered as a continuous variable, ranging from 25 to 54 years in 1984.

HIV antibody status. Participants' blood samples were examined independently by two laboratories with an indirect immunofluorescent antibody assay. Antibody-positive results were confirmed by using immunoblot tests. Baseline data included blood tests obtained in 1984 and 1985 (frozen sera from 1984 were tested in 1985), whereas follow-up data included HIV antibody status through 1989. There were seven seroconverters in this sample during the study period. Men who chose to receive HIV antibody results received standard posttest counseling. Previous analyses have shown that knowledge of antibody status did not influence risk behaviors in this cohort.[12]

Alcohol consumption. Data on alcohol consumption were obtained in 1989 for the respondents' drinking behavior during the previous 6 months. This scale was constructed to show the average volume of alcohol consumption per week. The mean amount of alcohol consumption in this sample was seven drinks per week, with scores ranging from 0 to 53. This scale was entered as a continuous variable, ranging from 0 to 53.

HIV-related health beliefs. Three types of beliefs were studied: perceived self-efficacy (four items, $\alpha = .58$), HIV transmission-related beliefs (two items, $\alpha = .45$), and perceived susceptibility to HIV/AIDS (two items, $\alpha = .85$). Participants were asked to indicate the amount of agreement with each item on the first two scales by using a 4-point scale ranging from "strongly agree" to "strongly disagree." Please see the Appendix for a list of health belief items and wording of response options.

Stress. This scale was designed to measure perceived stress in the past year and was administered in 1989. Areas assessed included perceived stress relating to the health of oneself and others, work, relationships, and finances. Participants rated each of the items on a four-point scale ranging from "none" to "a great deal" of stress (eight items, $\alpha = .61$).

Procedure

Attrition bias analyses were conducted by examining baseline rates for those subjects who remained in the study vs those who dropped out between 1984 and 1989. Dichotomous data were analyzed by using chi-square tests, whereas continuous data were analyzed with *t* tests.

The proportion of participants who identified themselves as bisexual at each of the study waves was compared with the proportion of men who reported having sex with both men and women at these times to examine the relationship between behavioral bisexuality and bisexual identity.

Sexual behavior prevalence rates were examined separately for HIV-positive and HIV-negative bisexual men in years 1 and 5. Sexual behaviors with men and women are described separately.

The association between the potential correlates and unprotected sex was examined by using backward stepwise multiple logistic regression, while controlling for age. The backward procedure was used to control for possible intercorrelations among the variables. Previous research[6] showed that age is an important predictor of high-risk sex among gay men in this sample. Controlling for age thus ensured that any other significant correlates contributed above and beyond the effect of age. For all scales, we compared scores separated by a fourth of the scale range (e.g., an interval of 3 points on a 12-point scale).

Results

Attrition Bias

We compared the participants seen in both 1984 and 1989 (n = 119) with the participants who dropped out (n = 21). No statistically significant differences were found. Both groups reported comparable rates of sexual behaviors in 1984–1985, with 78% and 27% of panel members reporting unprotected sex with men and women, respectively. The corresponding rates were 76% and 19% for dropouts. The mean age for both groups was 35 years. Forty-two percent of panel members and 43% of dropouts reported HIV-related symptoms. The two groups consumed similar amounts of alcohol (the mean number of drinks per week was 9.2 and 8.4, respectively). Forty-nine percent of the panel members and 67% of the dropouts were HIV positive.

Bisexual Behaviors and Identity

In year 1 of this study, 140 men identified themselves as bisexual. Thirty-seven of these men were also behaviorally bisexual during that time. An additional two men reported having sex with both men and women in year 1 but did not identify themselves as bisexual. In year 5 of this study, 119 men remained in our original cohort of bisexually identified men. Eight of these men were also behaviorally bisexual during that time. An additional three men reported having sex with both men and women in year 5 but did not identify themselves as bisexual.

Unprotected Anal and Vaginal Intercourse

All subject groups made significant risk reductions during this time period. The main differences appeared when comparing the gender of sex partners separately for HIV-positive and HIV-negative bisexual men. In 1984–1985, 89% of the HIV-positive men reported practicing unprotected anal sex with men, whereas 16% reported unprotected vaginal sex. By 1988–1989, 18% continued to report unprotected anal intercourse with men, and only 2% reported any unprotected vaginal sex with women.

Among HIV-negative men, a somewhat smaller proportion (65%) started out practicing unprotected anal sex with men. By year 5, this proportion was reduced to 20%, a figure comparable to that for HIV-positive men. The risk reduction was somewhat less pronounced for sex with women. In 1984–1985, 35% of these men reported engaging in unprotected vaginal sex, compared with 20% in 1988–1989. This means that in 1988–1989, 80% of all HIV-negative bisexual men who reported having sex with women (25% of the sample) reported having unprotected vaginal sex. This is a marked difference from their risk pattern with other men in 1988–1989. At that time, only 26% of the HIV-negative men who had sex with men (76% of sample) reported that they had engaged in unprotected anal intercourse.

Other Sexual Behaviors

The proportions of oral sex with men remained fairly constant among both HIV-positive and HIV-negative bisexual men. The percentage of HIV-positive men reporting this behavior decreased from 91% in 1984–1985 to 82% in 1988–1989. Among HIV-negative men it decreased from 83% to 76% during this time period. Slightly greater changes were seen in the percentage of men who reported oral sex with women. Among HIV-positive men, this percentage decreased from 23% to 7% and for HIV-negative men it decreased from 29% to 22%.

The percentage of men who reported sex with multiple (i.e., two or more) partners during a given year also decreased during the study period. The percent of HIV-positive men who reported multiple male partners decreased from 86% to 58%, whereas the percentage who had multiple female partners decreased from 7% to 2%. The percent of HIV-negative bisexual men with multiple male partners decreased from 63% to 51%, whereas the corresponding percentage with multiple female partners decreased from 21% to 8%. Finally, the prevalence of celibacy among all bisexual men increased from 4% to 13% during these 5 years.

Table 1 shows the proportions of participants who engaged in two different sexual behaviors during the same year in 1984–1985 and 1988–1989. The most drastic decrease occurred among men who engaged in unprotected anal intercourse and had multiple partners in year 1 (70%) and in year 5 (12%). In 1988–1989, very few (7%) men reported sex with men and women in the same year, compared with 26% in 1984–1985. The proportion of bisexual men who practiced unprotected sex with both men and women in the same year decreased from 16% to 2% of the sample.

TABLE 1—Percentage of Bisexual Men Who Reported Engaging in Multiple Sexual Behaviors during the Previous 12 Months (n = 119)

Sexual Behavior	Year 1 (1984–1985) %	Year 1 (1984–1985) No.	Year 5 (1988–1989) %	Year 5 (1988–1989) No.
Gender of sex partner				
Sex with men only	65	77	70	83
Sex with women only	6	7	10	12
Sex with both men and women	26	31	7	8
Celibate	5	6	13	15
Unprotected vaginal sex and multiple female partners	13	15	3	4
Unprotected anal sex with men and multiple male partners	70	83	12	14
Unprotected anal sex with women and multiple female partners	4	5	1	1
Unprotected anal sex with men and unprotected vaginal sex with women	16	19	2	2

TABLE 2—Cross-Sectional Correlates of Unprotected Anal and/or Vaginal Intercourse with Men or Women in 1989

Correlates	Odds Ratio	95% Confidence Interval
Age (10-y difference)	0.5	0.2,1.3
Self-efficacy	8.8	3.1,25.3
Susceptibility	1.3	0.6,2.8
Transmission beliefs	0.5	0.2,1.3

Stress	0.7	0.3,1.5
HIV antibody status (positive)	0.6	0.1,4.8

Note. The overall Hosmer-Lemeshow goodness-of-fit chi-square test for the final step in the backward stepwise logistic regression (which included only self-efficacy after adjusting for age) was 68.79 ($P = .485$). The P values for the chi-square test of the coefficients at this step were $<.0001$ for self-efficacy and .3034 for age. The odds ratios reported above are from the first step in the backwards procedure, which included all of the variables in the equation.

Cross-Sectional Correlates of Unprotected Sex

Table 2 shows the six variables entered into the multiple stepwise backward logistic regression analysis predicting unprotected intercourse in 1989. Due to small numbers, we decided to combine unprotected intercourse with men and women into one risk variable. High risk was thus defined as reporting any unprotected anal sex with men or women and/or reporting unprotected vaginal sex during the previous 6 months. Subjects were classified as low risk if they reported no unprotected sex with men or women during this time period. Perceived self-efficacy was the only significant correlate of unprotected sexual intercourse. High-risk subjects reported being significantly less confident of their ability to practice safe sex in a variety of situations than did low-risk subjects. Once perceived self-efficacy was entered into the stepwise model, it remained as a significant correlate. No other variables were statistically significant at any of the steps. However, although the remaining variables were not statistically significant, their wide confidence intervals suggest that it may be premature to exclude them as potential correlates of unprotected sexual intercourse.

Hypothetical Risk Situations

Participants were also asked to indicate retrospectively how likely they were to have anal sex without a condom with another man in nine hypothetical situations. The following situations were endorsed as either "very likely" or "somewhat likely" by the indicated percentage of study participants: sex while under the influence of alcohol or other drugs (37%), being in love with one's sex partner (35%), not having any condoms available (33%), having a partner who doesn't want condoms (30%), having sex with one's lover (29%), planning to withdraw before ejaculating (25%), perceiving condoms as making sex less enjoyable (23%), being under a great deal of stress (19%), and being sad or upset (18%).

Discussion

Single bisexual men in San Francisco have made dramatic changes in their sexual behavior. Some interesting differences emerged when we considered HIV antibody serostatus. Among HIV-positive bisexual men, most of the sexual risk taking appeared to occur with other men, with levels of unprotected anal sex being reduced from 89% in 1984–1985 to 18% in 1988–1989. Only 7% of the men in this group reported that they had engaged in any form of sexual activity with women in 1988–1989. Two percent reported having had unprotected vaginal intercourse, and no unprotected anal sex with women was reported in this group in 1988–1989. These changes are very encouraging. However, given that the HIV seroprevalence rates are approximately 50% among gay men in this age group in San Francisco, any unprotected sexual activity with a male partner of unknown HIV antibody status carries a high risk of HIV transmission.

HIV-negative men continued to be approximately three times more likely to engage in some form of sexual activity with men than with women in 1988–1989. Among those who did report sexual activity with women in year 5, unprotected vaginal sex appeared to be the norm, with 80% of these men stating that they had engaged in unprotected vaginal intercourse. In contrast, only 26% of those who had any kind of sex with men practiced unprotected anal sex. Possibly, bisexual men who are not infected with HIV perceive sex with women as less risky, thus representing an alternative to condom use during male-to-male sex as a method of HIV risk reduction.

It is unclear whether HIV antibody testing influenced behaviors in this study. Based on the data from the first wave of data collection (1984), it appears that men who later tested HIV negative had higher rates of sex with women (37%) and slightly lower rates of sex with men (83%) than did men who later tested HIV positive (23% and 93%, respectively). It is thus possible that their prior behavior may have contributed to the risk of infection. The decreased rates of sex with women (from 23% to 7%) and unprotected vaginal sex (from 16% to 2%) among HIV-positive men suggest that at least some of the HIV-positive men may have modified their sexual behaviors with women after their HIV antibody testing. It is important to note that these hypotheses are tentative and need to be rigorously tested in future studies before any firm conclusions can be drawn regarding the effect of HIV antibody testing in this population.

There was a striking reduction in the percentage of men who had unprotected anal sex and multiple male partners during the 5 years of the study (from 71% to 12%). Also, significantly fewer men reported having both male and female sex partners in 1988–1989 than in 1984–1985 (26% vs 7%). It is possible that much of this change is due to an increased tendency to have longer relationships and fewer sex partners. We were unable to examine this possibility directly because we have very limited data on relationships with men and no such data on female sexual partners. Because this issue has important implications for AIDS prevention campaigns, it needs to be examined in future research.

The analyses of psychosocial variables suggest that much risk taking is situationally determined. The self-efficacy scale included items assessing the amount of confidence the participants had in their ability to practice safe sex in different situations, such as "in the heat of passion" and "with an uncooperative partner." It should be noted that because these are cross-sectional analyses, it is possible that the participants were simply labeling their behavior during the past year when responding to these items. However, low self-efficacy has previously been found to predict sexual risk taking longitudinally in another San Francisco cohort of gay and bisexual men[7] and has also been associ-

ated with a variety of other health-related behaviors.[13,14]

The retrospective reports provided additional information regarding potential high-risk situations. The most frequently endorsed situations involved having sex under the influence of alcohol and other drugs, condom availability, and relationship variables such as one's feelings for and requests by a sexual partner. These results are very similar to results from other cohorts of gay and bisexual men.[15] The consistency of these findings suggests that some bisexual men may not perceive themselves as possessing the skills necessary for safe sex negotiation in high-risk situations. Finally, it is interesting that although alcohol consumption itself was not associated with unprotected sexual intercourse in the regression analysis, the combination of substance use (including use of alcohol) and sexual activity was perceived by the participants as an obstacle to safe sex. It thus appears that the role of alcohol and other drugs in connection with sexual activity needs to be addressed in AIDS prevention programs, even though we may not yet completely understand the nature of this association.

It is important to note that this study has some limitations. These results may not generalize to San Francisco men who have sex with both men and women but who do not identify themselves as bisexual. San Francisco Men's Health Study participants appear likely to be more open about their sexual orientation than other samples of perhaps more closeted bisexual men.[16] In spite of these differences, we find our results to be very encouraging and an example of how risk reduction may be facilitated in a culture in which most behaviorally bisexual men also identify themselves as bisexual.

Another limitation of this study was its small sample size, which prevented us from examining correlates of risk taking separately for the gender of the sex partner. It is thus possible that different factors influence risk taking during male-to-male and male-to-female sex.

In summary, the study population has drastically reduced sexual risk behaviors, especially during male-to-male sexual activities. Although unprotected vaginal intercourse is still the norm among those men who have sex with women, this behavior was reported almost exclusively by HIV-negative men. Thus we conclude that single, bisexually identified men in San Francisco do not appear to be a common vector for spreading HIV disease to women. □

APPENDIX—Health Belief Measures

1. Self-efficacy (agreement expressed on a 4-point scale)
   A. I am usually able to convince my sexual partner to have safe sex.
   B. If my partner refuses to use a condom, I still will have intercourse with him or her.
   C. I believe there is a lot I can do to prevent HIV transmission.
   D. In the heat of passion, I sometimes engage in sexual activities that are unsafe.
2. Susceptibility (degree of certainty expressed on 4-point scales, plus 1 N/A item [i.e., "I'm already infected" or "I've already been diagnosed"])
   A. How likely do you think it is that you will become infected with HIV in the future?
   B. How likely do you think it is that you will eventually get AIDS?
3. Transmission beliefs (agreement expressed on a 4-point scale)
   A. If both partners know that they have the antibodies (i.e., they both have positive test results), they can have any kind of sex without increasing their risk of getting AIDS.
   B. If both partners know that they do not have antibodies to the virus (i.e., they both have negative test results), they don't have to worry about practicing safe sex.

Correlates of Needle Sharing among Injection Drug Users

Wallace Mandell, PhD, David Vlahov, PhD, Carl Latkin, PhD, Maria Oziemkowska, MS, and Sylvia Cohn, MPH

ABSTRACT

Objectives. The sharing of contaminated injection equipment is the primary mode of human immunodeficiency virus (HIV) transmission for injection drug users. This study examined demographic factors, life events, and drug use practices that are potential risk factors for sharing injection equipment.

Methods. Between February 1988 and March 1989, 2921 active injection drug users were interviewed and questioned about their backgrounds, life-styles, and patterns of injection drug use.

Results. Of 2524 participants who reported injecting drugs within the 6 months prior to study enrollment, 70.4% reported recent needle sharing. A multivariate analysis found needle sharing to be more frequent among those with a history of arrest and lower socioeconomic status, even after accounting for other demographic and drug use variables. In addition, recent needle sharing was higher in male homosexual or bisexual men than in their heterosexual counterparts.

Conclusions. These data suggest that injection drug users have an economic motive to share needles and that the availability of free and legal needles may reduce levels of needle sharing. (*Am J Public Health.* 1994;84:920–923)

Introduction

Injection drug users are at increased risk for human immunodeficiency virus (HIV) infection. The primary mechanism for transmission of HIV infection among injection drug users is sharing contaminated needles and syringes.[1–4] Education about risk reduction and distribution of bleach for disinfecting needles have been important strategies against HIV infection in this population.[5,6] However, in one study, 98% of active injection drug users knew that HIV was transmitted through sharing needles, yet 70% reported sharing needles prior to the knowledge interview[7]; these data suggest that education is necessary but insufficient to effect behavior change. More recently, a study of the effectiveness of bleach on HIV seroconversion noted a modest protective effect for needle disinfection as it was being practiced in the field.[8] These results and others[9,10] underscore the need to study factors that contribute to needle sharing practices in order to identify characteristics that might lead to rational preventive interventions.

Information about risk factors for needle sharing is limited, and most of the information comes from participants in drug abuse treatment programs.[9,10] However, only a small proportion of injection drug users are in treatment at any given time, and characteristics of injection drug users in treatment differ from those of users who are not in treatment.[11] Corresponding information about factors associated with needle sharing is needed for the latter group. In 1988 and 1989, a large sample of injection drug users not in treatment was recruited through extensive community outreach techniques for a study of the natural history of HIV infection; we report here the correlates of needle sharing at time of entry into the study.

Methods

Study Population

The rationale, organization, and methods for the AIDS Link to Intravenous Experiences (ALIVE) Study have been described in detail elsewhere.[12] Briefly, between February 1988 and March 1989, injection drug users were recruited through extensive community outreach techniques. Brochures about the study were distributed at local drug abuse treatment programs, sexually transmitted disease clinics, emergency rooms, state parole and probation offices, homeless shelters, and subsidized housing projects. In addition, outreach workers from a local community health education organization distributed brochures, and study participants informed eligible contacts through word of mouth. Eligibility criteria were age older than 17 years, history of drug injection any time during the previous 10 years (to correspond to the interval when HIV was surmised to be present in the community), and no diagnosis of acquired immunodeficiency syndrome (AIDS) at baseline (as this was a longitudinal outcome).

Data Collection

After pretest counseling, informed consent, and venipuncture, participants underwent face-to-face interviews with a trained interviewer in a private room within the study clinic. The interviewer gathered information on medical history, drug use, and sex practices, as described elsewhere.[13] For this analysis we used sociodemographic information for the 10 years prior to interview, sexual orientation, and drug use practices during the 6 months prior to last use. Drug use practices included type and frequency of drug used, duration of injection drug use, the practice of "splitting" drugs (drawing up drugs in one syringe and squirting half into a second syringe, which is a practice used when two or more people with their own syringes buy drugs together). Needle sharing was defined by the question "With how many different people did you share a needle in the past 6 months?"; a response of zero defined a nonsharer and a response of one or more defined a needle sharer.

Following the interview, participants received risk reduction counseling, an appointment to return in 2 weeks for HIV antibody test results, and $10 compensation for time spent in the study. The study procedures were reviewed and approved by the Institutional Review Board of The Johns Hopkins School of Hygiene and Public Health.

Statistical Analyses

The binary variable, needle sharing, was cross-tabulated with other study variables; odds ratios were generated with 95% confidence intervals to guide interpretation. To simultaneously adjust for potentially confounding variables, we used logistic regression procedures.[14]

Results

Of the 3375 individuals who registered for the study, 378 (11.2%) did not qualify because they were younger than 18 years of age or did not report injection drug use in the previous 10 years. An additional 76 (2.5%) were excluded because of duplicate registration or disqualifying information obtained by further investigation. Of the 2921 eligible and consenting participants, 2597 (88.9%) reported using injection drugs within the 6 months prior to initial enrollment in the study; 2524 had complete information available. Characteristics of the 2524 with complete information and the 73 with at least one variable missing were statistically similar (data not shown).

[a]From logistic regression model presented in text, which controlled for demographic, life event, and drug involvement variables.

The risk factor analyses presented here are based on the sample of 2524 individuals who were active injection drug users in that they reported at least one intravenous injection in the 6 months prior to their initial visit to the study and who had no missing data. This group can be characterized as young (80% were between the ages of 25 and 44 years), male (81%), Black (90%), and currently unemployed (79%), with a history of imprisonment (66%) and homelessness in the past 10 years (49%), and often with no experience of treatment for drug abuse (48%) (Tables 1 and 2).

The subjects examined were active injection drug users: 40% injected at least daily and an additional 35% injected at least once a week; only 8% injected less often than once a month. Nearly one third attended shooting galleries (i.e., clandestine locations where needles and syringes are rented repeatedly). The predominant drug of choice for injection was cocaine (92%), although 77% used multiple drugs. Of the men, 9.6% engaged in homosexual or bisexual behavior and two thirds of these individuals, 6.4% of the men, had engaged in receptive anal intercourse within the last 10 years.

In univariate analysis (Tables 1 and 2), needle sharing was associated with almost all demographic (age and education), life-style (employment, public assistance, arrest), and drug involvement variables (drug of choice, frequency of injection, duration of use, experience of withdrawal symptoms, and participation in drug treatment). In particular, needle sharing was associated with younger age; users older than 45 years of age were less likely to share needles. Needle sharing was also associated with less education, current unemployment, and a history of having experienced homelessness, arrest, or imprisonment in the previous 10 years. The homosexual/bisexual male group had the highest proportion of individuals who had recently shared needles (81.6%). However, needle sharing was not statistically associated with either race or gender.

All variables examined in univariate analysis were entered into a logistic regression model to estimate the adjusted relative odds associated with that variable's contribution to needle sharing. After adjustment for all other variables, the only demographic variables that remained associated with needle sharing were younger age and education. Older and more educated individuals were less

likely to share needles. Among life-style variables, after adjustment for other variables, history of arrest in the previous 10 years, being on public assistance, and male–male sexual behavior remained significantly associated (i.e., the confidence interval excludes 1) with needle sharing. The variables describing current involvement with drugs (i.e., cocaine use, daily use, splitting drugs, and having experienced serious drug withdrawal symptoms) continued to demonstrate elevated odds for needle sharing after statistical adjustment. However, duration of injection drug use and history of treatment for drug abuse were not statistically associated with current needle sharing in the multivariate analysis.

Discussion

The primary mechanism for transmission of HIV infection among injecting drug users, needle sharing, has traditionally been viewed as a ritual firmly embedded within a subculture that is highly hesitant to change.[15] More recent study has suggested a pragmatic view that drug users also have an economic motivation to share needles.[10] The economic motivation is that drug users have limited funds and their priority is to obtain drugs. The findings of this study, which noted a higher proportion of needle sharing among the more economically disadvantaged drug users, are consistent with this pragmatic interpretation of needle sharing.

In addition to economic motivation, the finding of an association between needle sharing and history of involvement with the criminal justice system is consistent with a legal motivation to share needles. In particular, these data support findings of ethnographic studies that reported that drug users are hesitant to possess injection equipment that puts them at risk for arrest on charges of drug paraphernalia possession; prior experience with arrest and incarceration might serve as a deterrent to carrying injection equipment.[16,17] If so, the laws prohibiting possession of paraphernalia appear to have limited impact on illicit drug use per se, but they may have contributed to conditions that facilitate transmission of HIV infection. At the time paraphernalia laws were enacted, it is unlikely that this result was anticipated.

An alternate interpretation of the findings reported here is that persons who share needles are less socially competent and have fewer resources than those who do not share needles. Homelessness and being on public assistance can be considered as indicators of a seriously limited ability to function in society. Arrest is associated with lesser competence as a criminal. Such marginal individuals might be more dependent on others for access to drugs and injection equipment. The positive association of needle sharing and splitting drugs (a common practice among those who purchase drugs jointly with other users) could be consistent with this interpretation. Thus, needle sharing might to some degree be a marker of limited social competence. The public health implication is that resources are needed to engage this population.

The positive association between needle sharing and being a homosexual or bisexual injection drug user is disturbing. This finding suggests that this dual-risk group served as an important bridge for transmission of HIV infection to the injection drug–using community earlier in the epidemic.[18] Especially within minority communities, homosexual and bisexual men are relegated to lower status and therefore may be less able to control the conditions under which they use drugs. Although considerable efforts have been expended to establish prevention programs separately for homosexual men and injection drug users, additional special efforts are needed for homosexual and bisexual male injection drug users.

The positive association between needle sharing and higher frequency of injection and cocaine injection is indicative of the interrelatedness between intensity of drug use and risky injection practices. This interrelatedness underscores the importance of targeting interventions toward those with the highest levels of involvement with illicit drug use.

The findings of this study complement those of earlier studies that noted that needle sharing is frequent among injection drug users. Injection behavior is typically learned from more experienced

users.[19,20] A user's first drug injections are usually not planned[21] and typically require borrowing needles and taking instruction from a more experienced user who models the behavior. This initial joint use establishes early in the drug career a norm of sharing needles; continued needle sharing probably supports a social bond within injection drug–using groups. However, this study suggests that continued needle sharing is probably due also to pragmatic factors, including economic and legal motivations. Although the model for understanding needle sharing is likely to be complex, the results of this and other studies offer a basis for public health intervention. Recent studies of injection drug users show concern over personal health and intent to change high-risk practices[22,23]; trends in risk reduction have been observed.[24] Barriers to further change need to be addressed. Legal and economic barriers are reduced by needle exchange programs that offer unrestricted free and legal access to needles and syringes as part of a comprehensive HIV prevention program.[25] These data provide additional support for expanding needle exchange programs to provide a variety of outreach services to injection drug users. □

The Effects of Early Education Intervention on Maternal Employment, Public Assistance, and Health Insurance: The Infant Health and Development Program

Jeanne Brooks-Gunn, PhD, Marie C. McCormick, MD, Sam Shapiro, BS, April Ann Benasich, PhD, and George W. Black, PhD

ABSTRACT

Objectives. The purpose of this study was to test whether early education intervention influences maternal employment, education, fertility, and receipt of public assistance and health insurance.

Methods. The Infant Health and Development Program is a randomized trial of the efficacy of early education on the outcomes of 985 low-birthweight, premature children. Families in eight sites received either pediatric follow-up and referral (follow-up only group) or pediatric services plus early intervention services (intervention group) for the first 3 years of the child's life.

Results. Mothers in the intervention group were employed more months and returned to the work force earlier than those in the follow-up only group. Fertility and education were not associated with treatment. Mothers who had some college education received more months of public assistance in the intervention group compared with the follow-up only group. Mothers who were employed received more public assistance and public health insurance in the intervention group compared with the follow-up only group, when maternal employment was controlled.

Conclusions. Findings are discussed in terms of the recent emphasis on two-generational programs directed to providing health, welfare, and child care services to young children and their families. (*Am J Public Health* 1994;84:924–931)

Introduction

Early childhood intervention programs were developed to help close the gap between disadvantaged children and their more advantaged peers by raising poor children's levels of social and educational competence in anticipation of elementary school. Since the middle 1960s, federal, state, community, and university-based programs have been initiated. The most carefully evaluated (with the exception of Head Start) are the small-scale programs conducted by educational researchers.[1–7]

The programs vary on a number of dimensions—delivery setting (home, school, center, clinic); primary target (mother, child, both); timing of onset (prenatal, infant, toddler); intensity (amount of programming per week); extensivity (length of program); curriculum content; ratios of staff to children; and staff training. However, all programs focus on enhancing child competence. To do so, programs employ a variety of strategies, including (1) working directly with the child, (2) helping the mother improve her interactions and teaching skills with her child, (3) teaching the mother about problem-solving abilities and child rearing, (4) raising the mother's self-esteem and emotional functioning, (5) promoting a return to school or the job market, and (6) procuring health and educational services for the child. All strategies but the first one assume that altering the mother's behavior or attitudes will influence the child indirectly. Indeed, many scholars believe that the long-term success of programs does not depend on their ability to directly alter the cognitive abilities of the child in the preschool years but on their capacity to alter the environment in which the child lives—characteristics of the mother; economic or residential circumstances of the mother; or health, welfare, and educational services offered to the child through the mother's efforts.[8–12]

This idea has widespread support.[4,13,14] However, not all studies have evaluated effects of programs on the mothers; those that have often do not report these effects in the literature, but rather in the final project reports.[15–19] Additionally, many of the early intervention studies were begun in the late 1960s and 1970s, before the rapid increase of mothers of young children in the work force.[20] The provision of full-time, high-quality, center-based child care, as offered by many early intervention programs, is of great benefit to mothers wishing to return to work, especially in the early years of the child's life, when high-quality child care is in such limited supply.[21–23]

This article focuses on the effects on the mothers of early intervention services for families with a low-birthweight, premature infant, specifically with regard to maternal employment, education, and fertility, as well as the use of public assistance (Aid to Families with Dependent Children) and publicly funded health services (Medicaid). and Development Program, a randomized trial, offered home visiting from the time of the birth of a low-birthweight, premature child to the child's third birthday and center-based child development programming in the second and third years of life. Home visitors provided information on child development, health and safety, social and medical services, and problem-solving skills. The last two might contribute to receipt of public assistance, health insurance, and employment. The provision of full-time, high-quality child care might benefit employment and education. It was expected that full-time employment benefits and education benefits would be found, with the effects being more likely after the children are 12 months of age, the age at which center-based early intervention began. Stronger maternal employment effects were expected for the less-educated mothers, who often are unable to afford quality child care.[20,22,24] The provision of early intervention services also might affect the number of mothers receiving public assistance and using public health insurance.[25–27] Reductions would be expected, in part because of the fact that more mothers would be in the work force. At the same time, the Infant Health and Development Program staff might have helped women receive services for which they were eligible, which would result in more women from the intervention group receiving services. Although the intervention did not target fertility (as no family planning or maternal postnatal care services were offered), it could indirectly affect fertility via increased health care use. The hypothesis that the intervention indirectly causes a reduction in fertility was tested by comparing the proportion of mothers in the two groups who had a birth during the follow-up period.

TABLE 1—Comparison of Intervention and Follow-Up Only Groups at Randomization[a]: The Infant Health and Development Program

	Intervention (n = 366)[d]	Follow-Up Only (n = 595)[d]
Child characteristics		
Mean (SD) birthweight,[b] g	1819 (439)	1781 (468)
Mean (SD) score on neonatal health index[c]	100.7 (16.0)	99.6 (15.8)
Percentage male[b]	50	49
Maternal characteristics[d]		
Mean (SD) education,[b] y	12.0 (2.6)	12.4 (2.4)
Mean (SD) age,[b] y	24.6 (5.9)	24.9 (6.1)
Ethnicity,[b] %		
Black	53	52
Hispanic	10	11
White/other	37	37
Percentage employed (at randomization)	31	30
Percentage employed (before pregnancy)	80	79
Percentage in school (at randomization)	11	12

[a]No significant differences between groups.
[b]Randomization procedure included birthweight, gender, maternal education, maternal age, and maternal ethnicity.
[c]Neonatal health index is length of neonatal stay controlled by birthweight and site, standardized so that the mean = 100 and the SD = 16; high scores indicate better health.
[d]Numbers may vary because of missing data for maternal characteristics.

Methods

Design

The Infant Health and Development Program is a multicenter, randomized, controlled trial to evaluate the efficacy of an intervention consisting of early child development programs and family support services in reducing the prevalence of health and developmental problems among low-birthweight, premature infants (in this study, defined as infants with a birthweight of ≤ 2500 g and a gestational age of ≤ 37 weeks). The intervention model and the specific curricula used for low-birthweight infants in the Infant Health and Development Program were adapted from two longitudinal studies of early intervention with full-term children of low-income families: the Abecedarian Project and Project CARE.[28,29] Comprehensive child and parent curricula were delivered through home visiting, parent groups, and children's attendance at a child development center program. The two treatment groups were an intervention group that received all three of the above curricula plus high-quality pediatric follow-up through age 3 years and a follow-up only group that received only the pediatric follow-up. Referrals were made as necessary. Sites were responsible for assisting families, when needed, to obtain access to health care; three sites chose to provide primary care for their subjects.

The intervention program was initiated immediately after randomization on the infant's discharge from the hospital and continued until a corrected age of 3 years (i.e., the age was corrected for the estimated number of weeks premature). The protocol specified four home visits per month in year 1 and two visits per month in years 2 and 3. On average across all sites, families received about three visits per month in year 1 and 1.5 visits per month in years 2 and 3.[30] The child development centers provided the intervention group children with an enriched, extrafamilial, educational experience using a learning-game format beginning at 12 months (corrected age) and continuing until the last child at the site reached 36 months of age (corrected age). The children were scheduled to attend the center at least 4 hours daily, 5 days per week. The mean number of hours attended per day was 5. The comprehensive educational program emphasized cognitive, linguistic, and social development.[31]

The primary outcomes in the Infant Health and Development Program were related to the child's cognitive development and behavioral competence, areas in which low-birthweight premature infants are at risk for adverse outcomes. Secondary outcomes focused on mothers. The provision of the program's services may affect the families by allowing mothers to take advantage of educational or employment opportunities and to have increased access to and use of health care and community resources. Analyses on access to and use of health care services are reported in McCormick et al.[32]

Sample

Informed consent was sought from the parents of 1442 eligible infants at eight sites (sites are listed in Acknowledgements). Omitting one twin from each family and refusals, 985 infants were designated as the primary analysis group and constitute the cohort for the trial (see Table 1; for a description of the sample, see reference 33).

Infants were randomized to either the intervention group or the follow-up

only group immediately after hospital discharge, by use of a procedure that involved close monitoring for balance and for absence of bias.[34,35] The characteristics for which balance was sought were birthweight, gender, maternal age, maternal education, maternal race (Black, Hispanic, and White/other), primary language in the home, and infant participation in another study.[33,36,37]

Assessment Schedule

Children in both the intervention and follow-up only groups received pediatric surveillance, as offered through eight clinic visits at 40 weeks of gestational age and at 4, 8, 12, 18, 24, 30, and 36 months postterm age. These visits also were used to collect assessment data. All assessments were conducted in English.

Measures

Maternal outcomes. Outcomes include maternal employment, education, fertility, and receipt of public health insurance and public assistance. Mothers indicated whether they were employed, in school, or receiving public assistance at each clinic visit (4, 8, 12, 18, 24, 30, and 36 months postterm age). These data were used to calculate the cumulative months employed, in school, and receiving public assistance, as well as the timing of work force entry (focusing on the first entry mentioned, not on repeated entrances and exits). Mothers were asked whether they used public health insurance or had any health insurance at 36 months. The number of subsequent births was determined by the responses at the 12-, 24-, and 36-month assessments. Given the skewed nature of the distributions, fertility was coded as having had an additional child by the 36-month assessment (yes/no).

Initial status measures. Several initial status variables were examined because of associations with the primary outcome measures in previous research. Demographic factors include ethnicity, maternal education, and maternal age in years. Sites were examined because they differed on demographic factors.[33,38] Child characteristics were gender, birthweight, and score on a neonatal health index (a measure that standardizes the length of the neonatal hospital stay for birthweight and is converted into a scale with a mean of 100 and a SD of 16, with higher scores indicating better health).[39]

Data Analyses

Multiple linear regressions were performed to test for treatment group effects, controlling for the possible effects of the initial status variables just mentioned. Site was entered as seven dummy codes, and each site was compared with the eighth site. Maternal ethnicity was dummy-coded into two variables (Black vs Hispanic and White/other; Hispanic vs Black and White/other). Maternal education was coded as three categories (less than high school, high school graduation, and some college), maternal age in years, birthweight in grams, and neonatal health on a continuous scale. Additionally, possible interactions of the initial status variables with treatment group were examined in these regressions for all outcome measures.[33]

To see whether group membership influenced the timing of entry into the work force, we conducted Kaplan-Meier survival curve analyses. Additionally, we conducted subgroup analyses using multiple linear regressions to examine effects by ethnicity and education simultaneously. Mothers were divided into those with some college and those with a high school education or less. Effects for Black and White mothers were examined separately. Separate analyses for Hispanics with a high school education or less also were conducted. For these analyses, only sites with at least five families in the intervention group and five in the follow-up only group were included (see reference 38 for a description of the rationale for this procedure and descriptive statistics). Four sites were included for the group that was White and had some college (Arkansas, Harvard, Washington, Yale); four for the group that was Black and had some college (Arkansas, Einstein, Harvard, Pennsylvania); six for the group that was White and had a high school education (Arkansas, Einstein, Harvard, Texas, Washington, Yale); all eight for the group that was Black and had a high school education or less; and three for the group that was Hispanic and had a high school education or less (Einstein, Miami, and Texas).

Results

Maternal Employment

Cumulative months of employment. Mothers in the intervention group were employed for a greater number of months than were mothers in the follow-up only group (1.84 months, $P = .04$). This effect was net of site, demographic, and child characteristics, as found in the multiple linear regression analysis. Maternal age and race did not contribute to the cumulative number of months worked, although maternal education did (5.73 months per category of education, $P = .001$). The vast majority of the mothers in this trial were employed: 80% of the intervention group mothers and 72% of the Follow-up only group mothers worked at least 4 months out of the 3 years of the trial. At the same time, 16% of the intervention group mothers and 21% of the follow-up only mothers worked the entire 36 months.

Although no main effects of child characteristics were found in the multiple linear regression, a significant interaction between treatment and birthweight was found ($P = .02$). Investigation of the mean number of months that mothers worked for the two birthweight groups revealed that the treatment group differences appeared in the lighter, not the heavier, birthweight group. Mothers in the intervention group who had lighter infants (weighing 2000 g or less at birth) worked more months than mothers in the follow-up only group with lighter infants (mean of 18.1 months vs 15.3 months). Mothers of heavier infants (in the 2001- to 2500-g group) worked 14.3 months in the intervention group and 16.2 months in the follow-up only group.

Subgroup analyses indicated that the beneficial effect of the intervention on maternal employment occurred in mothers with a high school degree or less (Table 2). Black mothers were employed an average of 2.51 months more in the intervention group compared with the follow-up only group ($P = .05$); White mothers, an average of 5.05 months more in the intervention group compared with the follow-up only group ($P = .02$). (These differences are slightly different than those presented in Table 2, because they are based on the regression analyses controlling for initial characteristics, whereas the data in Table 2 are simple means.)

Timing of entry into the work force. The Kaplan-Meier survival analysis for timing of first reported entry into the work force by child's age (corrected for prematurity) is presented by treatment group in Figure 1. As can be seen, mothers in the intervention group were more likely to enter the work force somewhat earlier than the mothers in the follow-up only group ($P < .06$). The differences appeared when the children were 18 months of age.

Given the interaction between treatment and birthweight found in the analysis of cumulative months of employment, we examined the timing of the first

TABLE 2—Cumulative Months of Maternal Employment, Education, and Public Assistance, by Treatment Group, Maternal Education, and Ethnicity: Infant Health and Development Program

	Mean (SD) Employment, mo		Mean (SD) Education, mo		Mean (SD) Public Assistance, mo	
	INT (n = 300)[b]	FU (n = 486)[b]	INT (n = 308)[b]	FU (n = 500)[b]	INT (n = 307)[b]	FU (n = 500)[b]
Total sample	16.7 (12.9)	15.6* (14.2)	4.9 (9.0)	4.2 (2.6)	14.4 (15.8)	12.6 (15.2)
College education						
Black[a]	23.9 (11.2)	25.5 (13.0)	7.6 (12.4)	3.8 (7.6)	12.0 (16.1)	5.4** (11.1)
White[a]	22.4 (14.2)	21.8 (14.6)	2.4 (7.6)	4.1 (7.9)	3.2 (10.4)	0.2* (1.6)
High school education or less						
Black	14.1 (12.1)	12.0* (12.8)	6.2 (9.3)	5.0 (8.0)	20.6 (15.1)	20.3 (14.9)
White	18.1 (11.5)	14.0* (13.2)	2.3 (5.8)	2.9 (6.0)	8.4 (13.1)	9.5 (13.5)
Hispanic	7.7 (11.3)	9.9 (12.6)	7.5 (10.8)	3.5 (7.7)	22.8 (16.5)	20.4 (16.6)

Note. INT = intervention group; FU = follow-up only group.
[a]Means for education by ethnicity subgroup include mothers from those sites that had five or more families in both the intervention and follow-up only groups (see reference 36 and the text). Too few Hispanic mothers had some college to analyze.
[b]Numbers vary somewhat because of missing data (measures are aggregated over time)
*$P < .05$; **$P < .10$.

work-force experience reported after the child's birth for the lighter and heavier low-birthweight infants. For the infants with birthweights of 2000 g or less, mothers in the intervention group were likely to enter the work force earlier than those in the follow-up only group, with differences first emerging when the child was about 8 months of age ($P < .001$). In contrast, no significant differences were found for the heavier infants.

Cox proportional hazards analyses were used to test differences in timing of entry into the work force. Variables entered into the regressions were treatment, site, maternal characteristics (education, age, ethnicity), and child characteristics (gender, neonatal health status, birthweight). A significant treatment effect was found ($P = .05$), as mothers in the intervention group entered the work force earlier than mothers in the follow-up only group. Mothers with more education also entered the work force earlier than mothers with less education ($P = .0001$).

Maternal Education

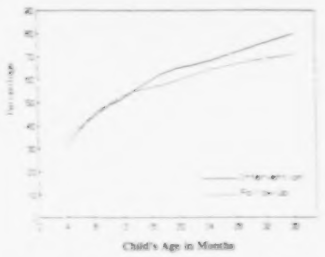
Multiple linear regression analyses on the cumulative number of months in school over the 3 years of the Infant Health and Development Program were conducted, paralleling the analyses for maternal employment. No significant treatment effect was found (Table 2).

The multiple linear regressions suggest that younger mothers spent more months in school than older mothers (0.33 months per year of age; $P = .001$), and Black mothers reported more months of schooling than other mothers (1.90 months, $P = .01$; see also Table 2). An interaction between treatment and race ($P = .04$) suggested that Hispanic mothers in the Intervention group received more months of education than those in the follow-up only group (4.8 months), whereas that was not true of the other two groups of mothers. No significant treatment effects were seen in the subgroup analyses.

Fertility

About one third (36%) of the total group of mothers had at least one additional birth in the 3 years since the target child's arrival (whether a subsequent birth had occurred was used in the regression rather than number of births because of the skewed nature of the distribution; numbers were 304 for the intervention group and 501 for follow-up only group). No treatment effect was found (2% fewer births in the treatment group; $P = .48$).

Not surprisingly, the multiple linear regressions suggest that younger mothers were more likely to have had a subsequent birth (2% of the women had an additional birth per year of age; $P = .0001$). Controlling for all other variables, Black and Hispanic mothers were somewhat more likely to have a subsequent birth (7% and 12%, respectively; $P = .08$ and $P = .06$, respectively). No interactions with treatment group were found, nor were any of the subgroup analyses significant. (To have an 80% chance of detecting a difference between the two groups (two-sided $\alpha = .05$), the absolute difference in proportions would have to be .10 or larger. The difference here was .02.)

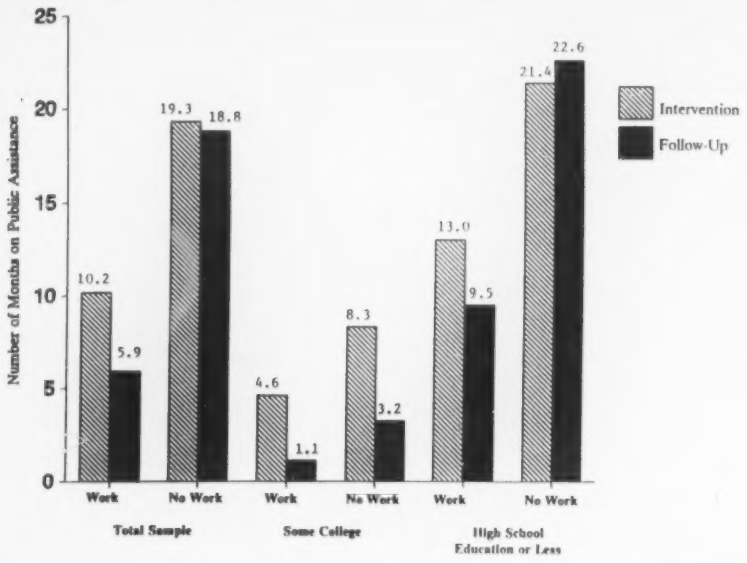


Note. Kaplan-Meier survival analysis. Child's age is postterm.

FIGURE 1—Timing of entry into the work force for mothers in the intervention and follow-up groups.

Public Assistance

Receipt of public assistance during the 36 months was not associated with treatment group. Large effects were found for ethnicity and education ($P = .001$ for each; see mean values in Table 2). However, a significant interaction between treatment and maternal education ($P = .005$) suggests that the more-educated mothers in the intervention group were more likely to receive public assis-



Note. Sample restricted to sites with five or more children in both the intervention and follow-up groups (see Brooks-Gunn et al.[38]). No Hispanics are included in the group with some college. Work groups: n = 395 for mother not employed (No Work); n = 402 for mother employed when the child was 36 months old (Work). Data are simple means based on subgroup analyses (maternal employment status when the child was 36 months old, treatment group, and maternal education when the child was born).

FIGURE 2—Number of months that mothers received public assistance, by treatment group, maternal employment status at 36 months, and maternal education.

tance than more-educated mothers in the follow-up only group. This was true for the Black subgroup (6.27 months more public assistance; $P = .07$) and the White subgroup (2.42 months more public assistance; $P = .02$).

In a separate regression analysis where maternal employment at 36 months was included as an independent variable, a significant treatment effect was seen ($P = 0.03$). That is, when controlling for maternal employment (which is highly negatively associated with the receipt of public assistance, as expected; $P = .005$), mothers in the intervention group were more likely to receive public assistance (1.78 months longer). A trend toward an interaction between treatment and employment ($P = .09$) suggests that mothers who were employed received more months of public assistance if they were in the intervention group compared with the follow-up only group (Figure 2). A significant interaction between maternal education and treatment group ($P = .04$) suggests that treatment group mothers who had some college education received more months of public assistance, but no association with treatment was found for mothers who had a high school education or less (Figure 2).

Public Medical Insurance

About 40% of the sample reported receiving public health insurance at the 36-month assessment (300 in the intervention group and 472 in the follow-up only group). Such receipt was not associated with treatment group. Overall, 82% of the mothers reported that they had some form of health insurance. Maternal ethnicity, education, and age were not associated with receipt of health insurance. No treatment effects for any form of health insurance were seen, either in the initial analyses or in the second set of multiple linear regressions when maternal employment was entered as a dependent variable. A significant interaction between maternal education and treatment group ($P = .05$) indicates that mothers with more education were more likely to have public health insurance when they were in the intervention group compared with the follow-up only group.

When maternal employment at 36 months is entered into the regression as a independent (control) variable, the intervention group was more likely to have public health insurance (the difference between the two groups was 7%; $P = .02$). A trend ($P = .08$) for an interaction between maternal employment and treatment group suggests that the treatment effects were found for the mothers who were employed at the 36-month point (Figure 3). An interaction between ethnicity and treatment group indicates that the effects were most pronounced for the Hispanic mothers ($P = .03$).

Discussion

Like other early childhood interventions in the first 3 years of life, the Infant Health and Development Program has the potential to influence mothers as well as children. This program differs from most previous studies of interventions that continue past the first years of life by focusing on a biologically vulnerable group—low-birthweight infants—rather than an environmentally vulnerable group—disadvantaged children.[2,40] However, about two thirds of the families in the Infant Health and Development Program were disadvantaged, as defined by low maternal education levels, and income. Children from these families are at increased risk for subsequent problems[10,41] and their mothers may be as well.[32] The inclusion of Hispanic and White families also is a welcome and significant departure from most of the early intervention literature, which focused primarily on Black families.[42,43]

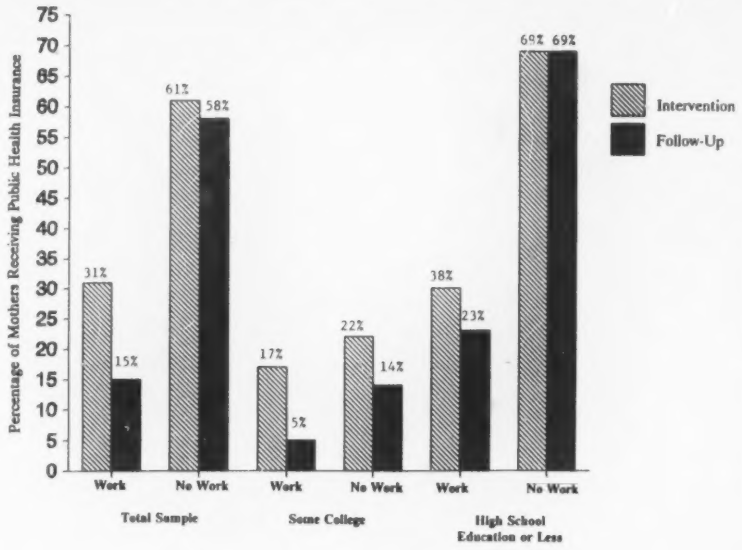
Results from the Infant Health and Development Program parallel those of previous studies with disadvantaged children in that the provision of early intervention services for children under the age of 3 years was found to increase the likelihood of maternal employment. As in other studies, these effects were modest but significant. Benasich et al. reviewed 27 programs providing educationally based intervention services in the first 3 years of life.[15] Of the 11 programs that reported on maternal employment as an outcome, all 5 home-based programs and 5 of the 6 center-based programs found that mothers in the programs were more likely to be employed or to be more stably employed than mothers in the comparison groups. Studies tend to report relatively small effects (e.g., treatment effects lasting less than 4 months). With respect to the timing of entrance into the work force, the

fact that group differences began to appear when children were 18 months of age suggests that the effect was primarily due to the provision of center-based care, which started when the child was between 12 and 13 months of age.[44]

Of importance is the fact that the maternal employment effects were found for mothers with a high school education or less. Other studies have not included mothers with college education. Mothers with less education (who earn less money) are probably unable to purchase high-quality child care,[20] making the Infant Health and Development Program very attractive.

Earlier studies did not examine timing of entry into the work force. Timing is particularly critical given the current debates about the effects of maternal employment and center-based care on children in the first year of life.[20,44,45] In the Infant Health and Development Program about half of the mothers of low-birthweight infants had entered the work force by the infant's first birthday, which is similar to the proportion reported in national samples of mothers.[20] When low-birthweight and normal-birthweight infants were compared by using the data for children in the National Longitudinal Study of Youth,[46] mothers with low-birthweight infants were somewhat less likely to place their children in outside-the-home care in the first year of life than were mothers with normal-birthweight infants.[47] Still, half of these mothers entered the work force during the first year of their child's life. In the Infant Health and Development Program, although actual birthweight was not associated with number of months worked, mothers of infants who had lower birthweights tended to enter the work force somewhat later than mothers of infants who weighed more ($P = .08$).

Of interest is the fact that being in the intervention group (as opposed to the follow-up only group) was associated with a longer period of employment for mothers with lighter low-birthweight infants but not for mothers with heavier low-birthweight infants. Generally, these results may indicate that mothers of lighter low-birthweight infants are reluctant to leave them for long periods of time or to put them in organized child care because the lighter children are sicker or are perceived to be sicker. Indeed, mothers in the Infant Health and Development Program did report that the lighter low-birthweight children experienced more hospital care (hospitalizations and number of hospital days), ambulatory care, and illnesses than the heavier low-birthweight children.[32,33] Thus, the family services provided to the mothers in the intervention group may have lessened their concerns about the health of the lighter low-birthweight infants, either through the information given in the home visits or the availability of high-quality, center-based care with excellent pediatric surveillance.



Note. Sample restricted to sites with 5 or more children in both the intervention and follow-up groups (see Brooks-Gunn et al.[38]). No Hispanics are included in the some-college group. Work groups: n = 382 for mother not employed (No Work); n = 390 for mother employed when the child was 36 months old (Work). Data are percentages based on subgroup analyses (maternal employment status when the child was 36 months old, treatment group, and maternal education when the child was born).

FIGURE 3—Percentages of mothers receiving public health insurance when the child was 36 months old, by treatment group, maternal employment status at 36 months, and maternal education.

Treatment effects were not found for schooling in the Infant Health and Development Program, unlike some of the previous interventions with disadvantaged children.[15] The intervention group mothers also did not differ from the follow-up only group mothers with respect to subsequent fertility. Mothers in the intervention group did not have lower fertility rates, but they also did not have higher fertility rates (a possibility, given the provision of free child care). Few earlier educational programs examined fertility, in part because family planning services were not offered in these programs. Only 15% of the 27 studies reviewed by Benasich et al.[15] included data on fertility. All reported positive effects and were comprehensive programs,[48–52] and two focused on teenage mothers and their children.[53,54] However, it is possible that longer-term fertility may be affected, rather than fertility at the completion of the program during the target child's toddler-hood years.[53–55]

Receipt of public assistance and health insurance were not examined as maternal outcomes in most of the early childhood intervention literature. However, our findings indicate that treatment effects were seen when maternal employment was controlled for. Of interest is the fact that mothers who were employed were more likely to receive these services when they were in the treatment group, suggesting that these mothers were eligible for public assistance and that the Infant Health and Development Program staff informed them of eligibility and procedures. These mothers presumably were employed in jobs that were low wage, part time, or "off the books." The ability of an early educational intervention program to improve access to health care via health insurance is relevant from a policy perspective, given that the number of families without health insurance

has increased.[26,56,57] Use of health care services was more frequent in the treatment group of the Infant Health and Development Program. These differences appeared at 12 months (results not shown), suggesting that the home-visiting component of the program played a role in the receipt of these services (because center-based schooling did not begin until 12 months).

A limitation of the study is the use of maternal report. Virtually all national studies rely on mothers to indicate employment, education, and fertility history. Reports of public assistance are fairly accurate (when compared with welfare records) over a much longer time period than that used in this study.[55] Additionally, the mothers in the Infant Health and Development Program were asked about these events every 4 to 6 months, which is a shorter recall period than that used in most studies.

Almost all early intervention programs postulate indirect or mediating effects of maternal and parenting outcomes on the child.[58] However, most employ a child-focused evaluation and only look at direct effects on the child. Indirect effects may constitute the "transmission pathways" for long-term effects on the child.[4,13,14] These include not only parenting behavior but also the ability to procure health, child care, and welfare services, as illustrated here. Additionally, enhancing maternal functioning is an important outcome in its own right.[9] Finally, more emphasis is being placed on two-generational approaches to providing services to poor young children and their families[59–61] in the hopes that both will benefit and that good maternal outcomes and service receipt will enhance the likelihood that the children will be positively affected.

The Family Support Act of 1988 is an excellent example of a focus not only on two generations but on integrated services. To help mothers leave the welfare system and enter the work force, they are offered education and job training as well as transitional child care (through a voucher system) and health insurance (through Medicaid). Both of the latter are critical in that the jobs for unskilled or semiskilled workers, such as young mothers with a high school degree or less, pay too little to purchase child care services and usually do not provide health insurance.[61] The results from the Infant Health and Development Program reported here illustrate that providing services to families—even though the focus is on the child and parenting behavior—has the potential to increase employment and to increase the receipt of health and welfare services for those not employed. □

Acknowledgments

The Infant Health and Development Program was funded by the Robert Wood Johnson Foundation. Additional support was provided from the Pew Charitable Trusts; the Bureau of Maternal and Child Health and Resources Development, Health Resources Service Administration; the National Institute of Child Health and Human Development; and the March of Dimes Birth Defects Foundation. Their generosity is appreciated.

The participating universities and site directors were Patrick H. Casey, MD, University of Arkansas for Medical Sciences (Little Rock, Ark); Cecelia M. McCarton, MD, Albert Einstein College of Medicine (Bronx, NY); Michael W. Yogman, MD, Harvard Medical School (Boston, Mass); Charles R. Bauer, MD, and Keith G. Scott, PhD, University of Miami School of Medicine (Miami, Fla); Judy Bernbaum, MD, University of Pennsylvania School of Medicine (Philadelphia, Pa); Jon E. Tyson, MD, and Mark Swanson, MD, University of Texas Health Science Center at Dallas; Clifford J. Sells, MD, and Forrest C. Bennett, MD, University of Washington School of Medicine (Seattle, Wash); and David T. Scott, PhD, Yale University School of Medicine (New Haven, Conn).

We thank Ruth Gross, Director of the National Study Office, and Craig Ramey, Director of the Program Development Office, Infant Health and Development Program, for their help. We also thank Rosemary Deibler for her assistance in manuscript preparation.

The Size of Mortality Differences Associated with Educational Level in Nine Industrialized Countries

Anton E. Kunst, MA, and Johan P. Mackenbach, MD, PhD

ABSTRACT

Objectives. This study addresses the question of whether inequalities in premature mortality related to educational level differ among countries.

Methods. Data on mortality by educational level were obtained from longitudinal studies from nine industrialized countries. The data referred to men between 35 and 64 years of age. The follow-up periods occurred between 1970 and 1982. The size of mortality differences associated with educational level was measured by means of two inequality indices, both based on Poisson regression analysis.

Results. Inequalities in mortality are relatively small in the Netherlands, Sweden, Denmark, and Norway and about two times as large in the United States, France, and Italy. Finland and England and Wales occupy intermediate positions. The large inequalities in mortality in the United States and France can be attributed in part to large inequalities in education in these countries.

Conclusions. The international pattern found in this study was also observed in a comparison that used occupation as the socioeconomic indicator. Differences between countries in levels of inequality in mortality may be partially explained by the countries' different levels of egalitarian social and economic policies. (*Am J Public Health.* 1994;84:932–937)

Introduction

Inequalities in mortality that are related to socioeconomic status are a generalized phenomenon in the industrialized world. In each country for which data are available, death rates have been found to be higher in groups with lower occupational status, educational level, or income level.

The question of whether these inequalities in mortality are about equally large in all countries or whether important differences exist has aroused wide interest. The primary reason for this interest is that inequalities in other countries provide a point of reference for judging whether health inequalities in one's own country are small or large. In addition, cross-country comparisons provide a unique opportunity to assess the effects of national socioeconomic policies on the magnitude of health inequalities.

Cross-country comparisons have traditionally used occupational status as the socioeconomic indicator.[1–8] Most of these studies were confronted with serious data problems, such as international differences in occupational classifications and a lack of information on the occupational class of large sections of the population (women, old men, middle-aged economically inactive men).[9] There is therefore a strong need to complement these studies with international comparisons that are based on other indicators of socioeconomic status.

The aim of the present study was to compare a large number of countries with respect to mortality differences associated with educational level. This study refers to men in the age group 35 to 64 years. Data were obtained from studies done in the United States and a number of European countries.

Methods

Data on mortality by educational group were acquired for as many countries as possible. Studies were selected that met the following criteria: (1) the study design was longitudinal, (2) the observation period occurred in the 1970s or the early 1980s, and (3) the study population was nationally representative. The selected studies[3,10–17] are presented in Table 1. The US study[17] consisted of a follow-up of eight samples of the Current Population Survey. The Dutch study[10] was an epidemiological follow-up study of military conscripts born in 1930. All other European studies selected were follow-ups of the national population census, either for a representative sample (England and Wales[14] and France[15]) or for the entire national population.

The length of follow-up in most studies was about 10 years. Studies with shorter follow-up times were also included because from analyses of data from the Netherlands, Finland, and France we found that the size of educational mortality differences does not change with increasing follow-up length.

Table 2 presents the educational classifications used in the respective stud-

ies. The average number of years of education was estimated by the authors in consultation with contact persons from the respective countries.

The educational level was not given for more than 1% of the populations of Denmark, Sweden, and England and Wales. In each of these cases, it was assumed that the educational level of this "unknown" group was equal to the level of the group with the lowest educational level. Support for this assumption in the Swedish case is that the occupational composition of the "unknown" group was similar to that of the group in the lowest educational category (Ö. Hemström and D. Vågerö, PhD, written communication, February 26, 1992). For Denmark, a comparison with more complete data from the Danish Health and Morbidity Survey suggested that the group with "unknown" education in the mortality study should have a low educational level. Because the mortality level of the "unknown" group in England and Wales was close to the national average, alternative assumptions about the group's educational level had a negligible effect on the measurement of the association between mortality and educational level.

Two other data problems are briefly mentioned here and will be discussed more extensively at the end of the Results section. First, the educational level of men in the Dutch study was assessed when they were 18 or 19 years old, that is, when some of them had still not left school. Second, more than two thirds of the population in Sweden, Finland, and England and Wales was assigned to a single (the lowest) educational category.

We compare countries by means of inequality indices that, for each country separately, measure the size of mortality differences associated with educational level. Indices were selected on the basis of two criteria: (1) all educational groups should be included separately in the calculation of the index, and (2) not all mortality differences should be measured, but only mortality differences that are systematically related to an ordering of educational groups from high to low socioeconomic status.[2]

These two criteria can be met by means of regression analysis. We applied Poisson (log-linear) regression, using the following regression model:

$$D_{are} = P_{are} \cdot e^{(\alpha_{ar} + \beta SES_e)},$$

TABLE 1—Studies Included in the International Comparison

Country	Reference	Follow-Up Period	Age Groups Distinguished, y[a]	Sample Size[b]
Netherlands	Doornbos & Kromhout[10]	1970–1981	38	79 000
Denmark	Andersen[11,c]	1970–1980	35–39, 40–44	289 000
Norway	Valkonen[12]	1971–1980	30–49[d]	141 000
Sweden	Vägerö & Lundberg[3,c]	1971–1980	35–39, 40–44, . . . 55–59	1 204 000
Finland	Valkonen[13,c]	1970–1980	35–39, 40–44, . . . 60–64	732 000
England & Wales	Fox & Goldblatt[14,c]	1971–1981	15–44, 45–64	162 000
France	Desplanques[15]	1975–1980	35–44, 45–54, 55–64	314 000
Italy	Pagnanelli[16]	1981–1982	18–54[d]	10 468 000
United States	Rogot et al.[17]	1979–1981	35–44, 45–54, 55–64	130 000

[a]Age at beginning of follow-up, except for England and Wales and France, where data refer to age at death.
[b]Number of male subjects at the start of follow-up in the given age groups.
[c]Data were obtained from unpublished tables.
[d]Mortality figures presented as age-standardized death rates or standardized mortality ratios.

where D is the estimated number of deaths, P is the number of person-years at risk, and SES is a measure of the socioeconomic status of each educational group. The subscripts a, r, and e denote 5-year age group, race (United States only), and educational group, and α and β are regression coefficients. The formula $(\exp\beta - 1)$ yields the inequality index used in this study. It represents the proportional increase in mortality per one unit increase in socioeconomic status.

The socioeconomic status of educational groups can be quantified in two ways. The first way is to quantify the educational level as the average number of years that are formally needed to complete that level. The corresponding inequality index represents the proportional mortality increase associated with 1 additional year's education. This index has been applied in an earlier international comparison.[12]

In the second method, the socioeconomic status of an educational group is conceptualized as the group's relative position in the social hierarchy. Following Pamuk,[18] this position is quantified as the proportion of the population that has a higher position in the social hierarchy. For example, if the highest educational group comprises 10% of the population, the relative position of its members would be between 0 and 0.10, the average being 0.05. The corresponding inequality index represents the proportional mortality increase associated with one unit increase in the relative position. More specifically, the index can be interpreted as the proportional mortality increase by moving from the top (= 0) to the bottom (= 1) of the social hierarchy.

We call the first index the partial inequality index and the second the total inequality index. These names are related to their interpretation, which can be illustrated as follows. If the score of a country on the total index is large compared with the scores of other countries, this implies large mortality differences between high and low positions on the social hierarchy. This large mortality difference can be attributed to large differences between high and low social positions in the number of years of education (i.e., large educational inequalities) or a large effect of 1 extra year of education on mortality (i.e., a large score on the partial inequality index). Thus, while the partial index measures the size of the effect of 1 extra year of education on mortality, the total index also takes into account the extent of inequality in educational levels themselves. The total inequality index therefore measures the total size of mortality differences in a population that are related to educational inequality. Since the two measures are complementary and each has a specific interpretation, both will be applied in the present study.

The regression equation assumes that mortality has a log-linear relationship with educational level. This assumption

TABLE 2—Educational Classifications Applied in the Various Studies

Country	Educational Groups	Average No. of Years of Education	% of Total Male Study Population[a]
Netherlands[10,b]	Primary education	8.0	48.2
	Lower vocational education	10.0	21.0
	Lower secondary education	12.0	17.8
	Higher level	15.5	12.9
Denmark[11]	9 years' education or less	8.0	27.8
	Educational level unknown	8.0	12.6
	10–12 years' education	11.0	40.0
	Vocational education, level unknown	11.5	7.1
	13–14 years' education	13.5	6.2
	15 years' education or more	16.0	6.3
Norway[12]	Primary school or not reported	7.5	38.9
	Second level, first stage	9.0	20.8

[a]At the beginning of follow-up.
[b]Educational level was assessed when the subjects were 18 or 19 years old.
[c]Percentages in the last column refer to the entire French population instead of the study population because the latter is based on a sample stratified by socioeconomic group.
[d]No reliable estimates are available for number of years of education corresponding to the educational groups used in the Italian study.
[e]Estimated from data on the same cohort in the survey Health Conditions of the Population and the Use of Health Services, 1986–1987.

was checked by means of (1) inspection of residuals and (2) the inclusion of a quadratic term for the education measure in the regression equation. No large departures from (log) linearity were observed.

Results

Total Inequality Index

Table 3 presents measurements of the total amount of inequality in mortality. The size of inequality decreases strongly with increasing age. Since the precise delimitation of age groups differs among studies, comparisons between studies cannot readily be made on the basis of Table 3. To facilitate comparisons, inequality estimates are presented in Figure 1 according to mean age at death.

At age 55 years and older, the smallest inequalities in mortality were observed for Sweden. The value of 0.36 for the oldest age group implies, according to the fitted regression equation, that death rates estimated for those at the bottom of the Swedish educational hierarchy are 36% higher than the death rates estimated for those at the top. Larger inequalities in mortality are observed for, in order of magnitude, England and Wales, Finland, the United States, and France. The total amount of inequality in France is almost four times as large as that for Sweden.

At ages below 55 years, the differences between Sweden, Finland, and France follow the same pattern but are less pronounced. The total amount of inequality in mortality is less than two times as large in France as in Sweden. The small inequality estimate for England and Wales and the very large estimate for the United States might have resulted from large chance fluctuations.

Data on inequalities in mortality below the age of 55 years were available for four additional countries. The inequality estimate for the Netherlands is considerably smaller than that for Sweden, while the estimates for Norway and Denmark are nearly identical to that for Sweden. The inequality estimates for Italy and France are equally large.

Partial Inequality Index

In Figure 2, countries are compared with respect to the partial inequality index, that is, the proportional increase in mortality associated with 1 additional year of education. Italy could not be included because of the absence of reliable data on the number of years of education.

The rank order of countries from small to large partial inequality estimates is the same as the order shown in Figure 1

for the total inequality estimate. The only exception is the United States, for which the total amount of inequality in mortality (total index) is large but the effect of 1 additional year of education (partial index) is relatively small. Among the European countries, the rank order of countries is the same for both inequality indices, but the differences in the total amount of inequality in mortality (total index) are much larger than the differences in the effect of 1 additional year of education on mortality (partial index).

As explained in the Methods section, large mortality differences related to educational level (the total index) can be attributed to a large effect of educational level on mortality (the partial index) or to large inequalities in educational levels. The results suggest that the former explanation seems not to hold for the United States and to hold only to some extent for France. This suggests that the large total amount of inequality in the United States and France is, at least in part, related to large inequalities in educational levels themselves.

To document this inference, we used a measure of inequality in educational levels that could be applied to the data for most countries: the average number of years of education of the top 20% of the population minus the average number of years of education of the bottom 80% of the population. According to this approximate measure, inequalities in education in the United States (5.75 years) and France (6.75 years) are indeed larger than those in other countries (e.g., England and Wales [3.75 years] and Sweden [4.25 years]).

TABLE 3—The Size of Mortality Differences Associated with Educational Level among Men, by Country and Age Group

Country	Total Inequality Estimate[a] (95% Confidence Interval)		
	Age 35–44 y[b]	45–54 y	55–64 y
Netherlands	0.72 (0.51, 0.95)[c]	. . .	. . .
Denmark	1.17 (1.02, 1.33)	. . .	. . .
Norway	1.02 (0.89, 1.16)[d]	. . .	. . .
Sweden	1.20 (1.02, 1.41)	0.60 (0.51, 0.69)	0.36 (0.28, 0.45)[e]
Finland	1.49 (1.32, 1.68)	0.99 (0.90, 1.08)	0.79 (0.71, 0.87)
England and Wales[f]	1.04 (0.43, 1.92)	0.75 (0.49, 1.06)	. . .
France[g]	1.97 (1.60, 2.39)	1.59 (1.31, 1.90)	1.28 (1.02, 1.56)
Italy	1.85 (1.75, 1.97)[h]	. . .	. . .
United States	2.62 (1.26, 4.78)	1.06 (0.51, 1.80)	1.05 (0.69, 1.48)

[a]The total inequality estimate represents the proportional mortality increase moving from the top to the bottom of the educational hierarchy.
[b]Age at beginning of follow-up.
[c]The men in the Dutch study were 38 years old.
[d]The men in the Norwegian study were 30 to 49 years old.
[e]The oldest age group in the Swedish study was 55 to 59 years.
[f]The age groups studied in England and Wales were approximately 10 to 40 years and 40 to 60 years.
[g]The age groups studied in France were approximately 32 to 41 years, 42 to 51 years, and 52 to 61 years.
[h]The men in the Italian study were 18 to 54 years old.

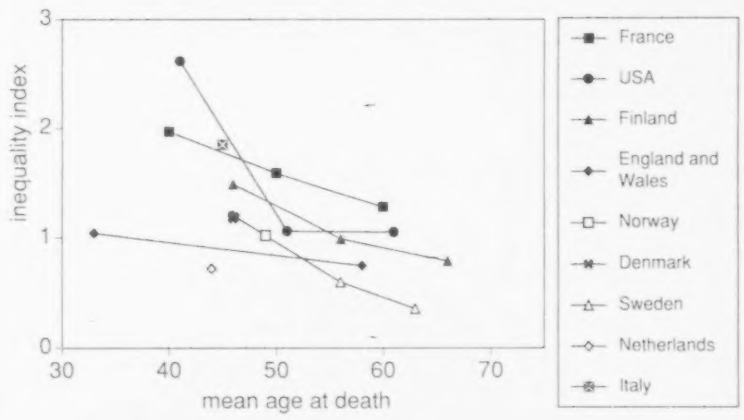

FIGURE 1—Total inequality index, by country and age group.

Evaluation of Potential Sources of Bias

Two potential sources of bias were briefly mentioned in the Methods section.

First, the educational level of subjects in the Dutch study was determined in 1950, when they were 18 or 19 years old. The level of education that an 18- or 19-year-old man had completed in 1950 was probably closely related to the educational level that he finally would achieve. However, discrepancies may exist, which implies misclassification of subjects. The most likely effect of such misclassification on inequality estimates is underestimation. Perhaps the underestimation is so large that it explains the relatively small observed inequalities for the Netherlands. We therefore feel that there is insufficient evidence to conclude that inequalities are smaller in the Netherlands than in Scandinavian countries.

Second, more than two thirds of the population of Sweden, Finland, and England and Wales was assigned to a single (the lowest) educational category. As a consequence, the relationship between mortality and educational level within a large segment of the population could not be included in the calculation of the inequality indices. Therefore, the inequality estimates are less accurate for these countries than for other countries. Perhaps, however, this problem is less serious than it seems. Recall that the relationship between mortality and educational level is approximately linear. This implies that approximately the same regression estimates would be obtained whether 4 or, say, 10 educational groups are distinguished. We found support for this expectation in additional analyses on all countries with detailed educational classifications. We reestimated inequality indices after combining the lower 80% of the population into one large educational category. Despite this substantial loss of information, the new inequality estimates

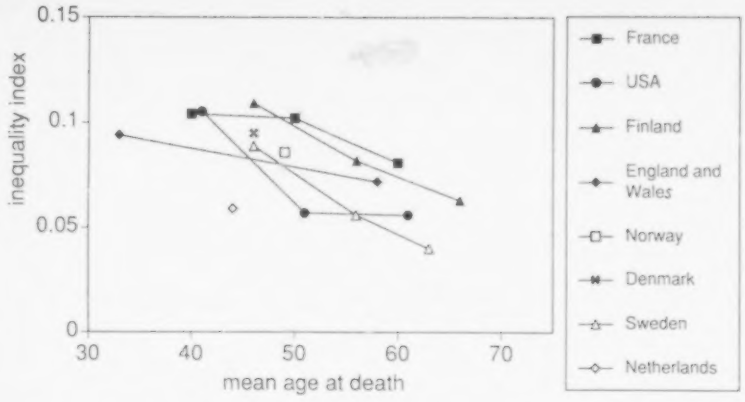

FIGURE 2—Partial inequality index, by country and age group.

were nearly the same as the estimates that were based on detailed educational classifications (less than 10% difference).

Discussion

An important question for the evaluation of socioeconomic inequalities in health is the extent to which these inequalities can be regarded as variable. This question has often been approached by time-series analysis, which has shown for various countries an increase in inequalities in mortality during the postwar period.[12,15,18–22] We chose a different approach by addressing the question, To what extent do inequalities in mortality vary across countries? Substantial cross-country differences were observed in the size of mortality differences associated with educational level. Differences are relatively small in the Netherlands, Sweden, Denmark, and Norway and about two times as large in the United States, France, and Italy. Finland and England and Wales occupy intermediate positions.

In addition, we investigated to what extent the large mortality differentials in the United States and France can be attributed to relatively large inequalities in educational levels themselves or to a large effect of educational level on mortality. We found that international variations in the size of inequalities in educational levels are most important, whereas the effect of education on mortality is approximately equally large in all countries.

The latter finding corroborates the fascinating finding of Valkonen's comparative study of England and Wales, Hungary, and the Scandinavian countries.[12] Valkonen found that in the 1970s, at ages below 50 years the relationship between education and mortality was "surprisingly similar": in each country death rates diminished by about 8% with an increase of 1 year in educational attainment. He warned, however, that this finding should not be taken as evidence of a "universal law" of health inequalities, because large cross-country differences were observed for specific causes of death and, in addition, might be observed for other time periods or other age groups. Indeed, we found that at ages older than 50 years, the effect of 1 year of additional education on mortality varied substantially among countries, with the effect in France being two times as large as that in Sweden.

We used education as the socioeconomic indicator because this indicator has been judged to be more comparable internationally than occupation.[9] Although in individual populations education and occupational status are strongly correlated,[23] the question remains whether the same international pattern of inequalities in mortality would be found if occupation were used as the socioeconomic indicator. The answer is probably affirmative: a recent study comparing seven European countries with respect to occupational mortality found virtually the same rank order of countries from small to large inequalities: (1) the Netherlands, Denmark, Norway, and Sweden; (2) England and Wales; (3) Finland; and (4) France.[24]

Cross-country comparisons provide a new opportunity to identify circumstances that are associated with large or small mortality differentials. A relevant question, therefore, is why the extent of inequalities in premature mortality varies among countries.

The first line of explanation relates to the selection hypothesis, which states that health and education are related in part because educational achievement depends on, among other things, health or health-related factors. The contribution of health selection to the generation of inequalities in adult mortality has been much disputed but is bound to be the subject of conjecture as long as lifelong longitudinal studies are not carried out.[25,26] Important for the present study is that the magnitude of health selection is likely to vary among countries as a function of educational and training structures.[26] Lahelma and Valkonen posited a more specific hypothesis: In countries where people coming from different strata have more equal access to education, the achieved educational level may depend less on social background and more on personal characteristics, including health and health-related factors. Paradoxically, then, health and education may be relatively closely related in open, competitive societies.[27] Testing this hypothesis requires detailed assessment of international variation in educational and training structures, which is outside the scope of this paper. The hypothesis may partially account for the fact that the United States, where intergenerational social mobility is larger than in nearly any other industrialized country,[28] is also one of the countries with the largest inequalities in both mortality and morbidity.

The alternative line of explanation relates to the causation hypothesis, which stresses the effect of educational level on health. The higher death rates of lower-educational-level groups are explained at least in part by a higher prevalence of risk factors for disease, such as factors related to life-styles, material living conditions, working conditions, and ways of coping with stress. A logical extension of this assertion is that international variations in the social distribution of risk factors explain, at least in part, the international variation in inequalities in mortality.

An illustration is offered by France and Italy. Leclerc et al. showed that diseases related to alcoholism and alcohol abuse accounted for a substantial part of the excess mortality of lower social classes in France, whereas their role is much more limited in Finland and in England and Wales.[1,29] Italian data suggest that to an important extent, the large mortality differences in Italy are also attributable to

excessive alcohol-related mortality among members of lower socioeconomic groups.[16]

Explanations cannot be confined to risk factors for disease, but should also consider the more distal social, economic, and cultural factors. One potentially relevant factor is welfare and income policies. Wilkinson's work is particularly relevant here.[30,31] He demonstrated that national death rates are strongly related to the extent of income inequality, and he inferred from this finding that large income inequalities are associated with large inequalities in mortality. Our study allows for a first test of this hypothesis. During the 1970s, income inequalities were relatively large in the United States, France, and Italy and approximately equally small in the other countries.[32,33] Income inequalities in Finland, still large in the 1960s, diminished rapidly during the 1970s. This rank order of countries in terms of income inequalities strongly corresponds to their rank order in terms of inequalities in mortality. Thus, our material corroborates Wilkinson's inferences. A main challenge to future international comparisons is to determine whether this association is spurious or reflects a true positive effect of egalitarian social and economic policies. □

Acknowledgments

This study would not have been possible without the unpublished data supplied by the following persons: Otto Andersen (Danish data), Denny Vågerö (Swedish data), Tapani Valkonen (Finnish data), and John Fox and Haroulla Filakti (data on England and Wales). Recent publications on France were supplied by Guy Desplanques. We thank Tapani Valkonen, Annette Leclerc, John Fox, Haroulla Filakti, and Denny Vågerö for their detailed comments on an earlier version of this paper.

Why Did Black Life Expectancy Decline from 1984 through 1989 in the United States?

ABSTRACT

Objectives. The objective of this study was to partition the change in US life expectancy into those major causes of death and age groups that contributed most to the decline in life expectancy for Black males and females and to the increase in life expectancy for White males and females in the period from 1984 through 1989.

Methods. By means of a life table partitioning technique, the positive and negative contributions of age and cause of death to changes in life expectancy were estimated.

Results. Causes contributing most to the decrease in life expectancy for Black males included human immunodeficiency virus (HIV) infection (<5 and 20–69 years of age) and homicide (1–4 and 10–34 years of age); for Black females the causes included HIV infection (<5 and 20–59 years of age) and cancer (65–79 and ≥85 years of age).

Conclusions. Mortality trends between the two major race groups in the United States diverged sharply, and without precedent, during the late 1980s. A description of these trends in terms of contributions to change in life expectancy may help us better analyze and interpret changes in the health of these groups and may contribute to a better allocation of resources for research, education, and public health programs. (*Am J Public Health.* 1994;84:938–944)

Introduction

Since 1900, life expectancy at birth in the United States has generally increased for males and females and for both major race groups—the White and Black populations. However, from 1984 through 1989 a countervailing trend drew wide public attention: whereas life expectancy generally increased for both White males and females, it decreased for both Black males and females[1] (Table 1).

In this research, we partition the changes in life expectancy at birth into those major causes of death and age groups that contributed most substantially to the decline for Black males and females and to the increase for White males and females. Also examined separately are the changes in the "gap," or difference, in the life expectancy between Black and White males and between Black and White females for the same time period.

The analysis uses a life table disaggregation technique developed by Eduardo E. Arriaga[2,3] to "measure the pace of mortality change . . . as well as the decomposition of a difference in life expectancy."[2(p95)] A summary measure like life expectancy is a convenient measure of the mortality of a population. Life expectancy has the advantage of ready interpretation.[4]

Methods

To measure changes in mortality, Arriaga[2,3] developed a method to estimate the contributions of age and cause of death to changes in life expectancy, which he describes as a procedure that "estimates the number of years added to or removed from life expectation because of the decrease or increase (respectively) of the central mortality rates of life tables."[3] This method partitions the changes in life expectancy over time or between two separate groups of populations. In this report Arriaga's technique is used to partition changes in life expectancy at birth in the United States by age and cause of death from 1984 through 1989 for the total population and for the four major race-sex groups. These changes in life expectancy by race, sex, and age are partitioned into component additive parts.

The causes of death used in this study are based on the 15 leading causes of death in 1984 and 1989 for the total population and for each of the four major race-sex groups, resulting in a total of 17 causes. All other causes are in a residual category. The codes and complete titles of the causes of death consistent with the *Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death*, Ninth Revision (ICD-9)[5] are shown in the Appendix. Cause-of-death rankings are based on the National Center for Health Statistics' "List of 72 Selected Causes of Death"[6] and the category of human immunodeficiency virus (HIV) infection (category numbers *042–*044), which was added to the lists of rankable causes effective with data year 1987. Further information on cause-of-death lists and rankable causes can be obtained from the Technical Appendix

section of *Vital Statistics of the United States.*[6] The number of deaths from HIV infection in 1984 was estimated by using the number of deaths reported with mention of ICD-9 code 279.1 (deficiency of cell-mediated immunity).

Because the changes in life expectancy, expressed in years, are relatively small when partitioned into age groups and causes of death, life expectancies were recomputed and are presented to three significant digits after the decimal.

TABLE 1—Life Expectancy (in Years) at Birth, by Race and Sex: United States, 1970 through 1989

		White			Black		
Year	Total Population	Both Sexes	Males	Females	Both Sexes	Males	Females
1989	75.3	76.0	72.7	79.2	69.2	64.8	73.5
1988	74.9	75.6	72.3	78.9	69.2	64.9	73.4
1987	75.0	75.6	72.2	78.9	69.4	65.2	73.6
1986	74.8	75.4	72.0	78.8	69.4	65.2	73.5

1971	71.1	72.0	68.3	75.8	64.6	60.5	68.9
1970	70.8	71.7	68.0	75.6	64.1	60.0	68.3

Note. Data are rounded to the nearest 0.1 year as published.[1]

Results

By Age

From 1984 through 1989, life expectancy at birth increased for the total population by 0.6 year (Table 1).[1] During the same period, life expectancy at birth increased for both White males and White females (by 0.9 and 0.5 year, respectively) but decreased for both Black males and Black females (−0.8 and −0.2 year, respectively).

Changes in life expectancy over time can be viewed as the net effect of "positive contributions" and "negative contributions" to life expectancy. Positive contributions result from declining death rates specific for age, race, sex, and cause of death, whereas negative contributions result from increasing death rates specific for these categories. Positive contributions from declines in one cause of death can be entirely offset by negative contributions from another cause for the same population group.

From 1984 through 1989, for the total population (males and females of all races combined), life expectancy at birth increased by about half a year, or 0.513 year (Table 2, "By Age"), as a result of positive contributions for the age groups under 15 and 45 or more years old, which more than offset negative contributions for the age groups from 15 through 44 years old. Similar positive and negative contributions occurred for White males and White females (data not shown). For Black males (data not shown), life expectancy declined in the period from 1984 through 1989 by −0.730 year, reflecting negative contributions for ages under 5, 10–54, 75–79, and 85 years and over, offsetting positive contributions for other age groups. For Black females (data not shown), life expectancy declined −0.178 year, reflecting negative contributions occurring at ages under 5, 10–45, 65–69, 75–79, and 85 years and over, also offsetting positive contributions in the other age groups.

By Cause of Death

For the total population, the cause of death with the largest positive contribution to the change in life expectancy in the period from 1984 through 1989 (Table 2, "By Cause") was heart disease, followed by cerebrovascular disease (stroke). These positive contributions were partially offset by negative contributions for other causes of death, the largest of which were for HIV infection, diabetes mellitus (diabetes), and pneumonia and influenza (pneumonia).

For White males (data not shown), heart disease contributed the most, followed by stroke and accidents and adverse effects (accidents). For White females the pattern was similar to that of White males.

Although life expectancy increased from 1984 through 1989 for both White males and females, it declined for Black males and females. For Black males (data not shown), the greatest negative contributor was HIV infection, followed by homicide and legal intervention (homicide). For Black females, the major causes of the decrease in life expectancy were HIV infection, diabetes, and pneumonia.

By Age and Cause of Death

A more comprehensive way to examine contributions to the change in life expectancy is to combine causes of death and age groups. Thus, for some causes of death (e.g., cancer) there were positive contributions for some age groups and negative contributions for other age groups.

For the total population, over half (59.4%) of the positive contribution to the change in life expectancy from 1984 through 1989 was due to changes in mortality from heart disease for ages birth through 1 year and 35 years and over (Table 2, "By Age and Cause"). Also making a large contribution were stroke for ages 40 years and over and cancer for ages 30–59 years. These three causes of death accounted for over three fourths of the positive contribution to the change in life expectancy during this period. Negative contributions for the total population were largely attributable to HIV infection, which accounted for one third of the negative contribution to the change in life expectancy in the period from 1984 through 1989. For this cause, the negative contribution was concentrated in persons aged 20–59 years. Cancer for ages 65 years and over accounted for 9.3% of the negative contribution. Pneumonia for ages 75 years and over accounted for 8.6% of

[c]Number of resident deaths due to human immunodeficiency virus infection in 1984 was estimated by using the number of death certificates with mention of ICD-9 code 279.1.

the negative contribution. Diabetes also showed a negative contribution for ages 45 years and over.

Causes of death may show sizable positive contributions for some age groups and sizable negative contributions for other age groups. This is particularly the case for cancer. Decreasing mortality from cancer for persons aged 30–59 years made a 6.3% positive contribution to the change in life expectancy from 1984 through 1989, whereas for persons aged 65 years and over, increasing mortality from this cause contributed 9.3% to the negative change in life expectancy. However, for most causes of death, the contributions of the age groups tend to be generally positive or negative.

White males showed a pattern similar to that of the total population (Table 3), with a total positive contribution of 59.1% from the age-cause combinations of heart disease for ages under 1 year and 35 years and over; stroke for ages 45 years and over (7.8%); and accidents for ages 1–4, 10–34, and 45–54 years (7.0%). Negative contributions to life expectancy were dominated by HIV infection for ages 20–64 years, representing 55.6% of all negative contributions.

For White females (Table 3), causes of death making large positive contributions were heart disease for ages under 1 year and 40 years and over, stroke for ages 40 years and over, and cancer for ages 30–59 years. Dominating the negative contributions for White females (unlike White males) were chronic obstructive pulmonary diseases and allied conditions for ages 55 years and over, cancer for ages 60 years and over, and pneumonia for ages 65–69 years and 75 years and over.

For Black males (Table 4), heart disease for ages under 1 year and 25 years and over had a major positive impact, as

[a]Includes age groups that contributed at least 1 day to the change in life expectancy.
[b]May include positive (or negative) changes for age groups not shown.
[c]Number of resident deaths due to human immunodeficiency virus infection in 1984 was estimated by using the number of death certificates with mention of ICD-9 code 279.1.

did cancer for ages 30–49 and 55–64 years and stroke for ages 30–34 and 40 years and over. A striking effect was that of homicide at ages 45–64 years, which contributed positively to the change in life expectancy. Negative effects for Black males were dominated by HIV infection for ages under 5 and 20–69 years; homicide for ages 1–4 and 10–34 years; and accidents for ages under 1 year and 15–24, 35–54, and 60–64 years.

For Black females (Table 4), three fourths of the positive contribution to the change in life expectancy from 1984 through 1989 was due to the three leading causes of death: heart disease for ages under 5 and 35–84 years, stroke for ages 35 years and over, and cancer for ages 25–29 and 40–59 years. Negative effects were led by HIV infection for ages under 5 and 20–59 years, cancer for ages 65–79 and 85 years and over, and diabetes for ages 45–69 and 75 years and over.

Change in the Gap in Life Expectancy between Whites and Blacks

Historically, Black life expectancy has, on the average, increased more rapidly than White life expectancy, resulting in a narrowing over time in the gap in average length of life between the two groups. But in the period from 1984 through 1989 the gap or difference in life expectancy between White and Black males increased by 1.7 years from 6.2 years to 7.9 years (Table 1). Contributing most to the growing gap in life expectancy between males of the two race groups were trends in mortality for heart disease for males 40 years and over (Figure 1). Although the change in life expectancy from this cause increased for both White and Black males, it increased less rapidly for Black males, resulting in a negative contribution of 23.2% of the widening gap. The next two most important causes contributing to the widening gap were HIV infection (for ages under 5 and 20–64 years) and homicide (for ages 1–4 and 10–39 years), for which decreases in the change in life expectancy were greater for Black males than for White males, resulting again in negative contributions to the gap in life expectancy.

Some causes of death and age groups kept the gap between Black and White males from widening more than it did

Note. Data are based on recomputed life expectancies at birth rounded to the nearest 0.001 year. COPD = chronic obstructive pulmonary disease.
[a]Includes age groups that contributed at least 1 day to the change in life expectancy.
[b]May include positive (or negative) changes for age groups not shown.
[c]Number of resident deaths due to human immunodeficiency virus infection in 1984 was estimated using the number of death certificates with mention of ICD-9 code 279.1.

(Figure 1). Among these were trends in mortality for cancer for males aged 35–49 and 55–64 years, which made a positive contribution of 32.2% to narrowing the gap. Also contributing to the narrowing were stroke for ages 55–59 and 65–74 years (11.6%) and homicide for ages 45–64 years (9.5%).

From 1984 through 1989 the gap in life expectancy between White and Black females also increased, by 0.7 year, from 5.0 years to 5.7 years (Table 1). Contributing most to the growing gap in life expectancy between females of the two race groups were trends in mortality for heart disease for ages 60 years and over (Figure 2). Although the change in life expectancy from this cause increased for females of both races, it increased less rapidly for Black females, resulting in a negative contribution of 27.5% to the widening gap. For the next most important cause contributing to the widening gap—namely, HIV infection (for ages under 5 years and 20–64 years)—decreases in the change in life expectancy were greater for Black females than for White females, resulting in a negative contribution to the widening gap in life expectancy. These two causes in the age groups mentioned contributed 43.2% to the widening gap in life expectancy between White and Black females.

Countervailing effects to the widening of the gap were mortality trends for cancer for females aged 25–29, 40–44, 50–64, 70–74, and 80–84 years, which contributed to the narrowing of the gap. Also contributing to the narrowing were chronic obstructive pulmonary disease for ages 60–64 and 70 years and over and heart disease for ages 35–44 and 50–59 years.

Discussion

A major change occurred in US patterns of mortality from 1984 through 1989: whereas life expectancy for the total population continued the general increase that has occurred since the beginning of the century, for the very first time there was evidence of strong and persistent divergence in the mortality patterns

between the two major race groups, the White and the Black populations. Life expectancy increased for White men and women but decreased for Black men and women. Never before has this pattern occurred in the United States over a sustained period. Previously, mortality patterns for the two major race groups have been upward, with the Black death rates improving more rapidly than the White rates. This trend has resulted, historically, in a convergence in mortality between the two groups. But during the period from 1984 through 1989, this pattern was reversed.

The results show that from 1984 through 1989 the trends and patterns in mortality between the White and Black populations were sufficiently different to result in differences in the change in life expectancy. For the White population, improvements in heart disease, stroke, and accident mortality were sufficient to offset the negative trends of other causes. However, for the Black population, the negative impact of HIV infection, homicide, diabetes, and pneumonia overwhelmed improvements in mortality from other causes.

It should be noted, and may come as a surprise, that the greatest contributions to the widening gap in life expectancy between the two major race groups were made by a cause of death for which the trends are favorable: heart disease. For both race groups, mortality from this cause is declining, but it is declining so much more rapidly for the White than for the Black population that this is causing the gap to widen.

Obviously, changes in mortality patterns are highly complex, particularly when examined separately for males and females of each of the major race groups and then by age and cause of death. A major contribution to articulating and understanding these changes is the life table partitioning method developed by Eduardo E. Arriaga. This method provides a clear way to define in demographic and medical terms the major mortality problems in the United States and to suggest where prevention efforts might have their greatest impact.

This analysis has focused on changes in mortality by race, a variable that is widely used in health statistics to classify the population. Many studies suggest that race may be a proxy, in part or substantially, for social and economic factors such as educational attainment, income, occupation, and life-style.[7,8] As such, the results described in this article may be indicative of changes occurring in the social fabric of society regardless of race, rather than being specific to one racial group or another. Our results are consistent with those of Pappas et al.,[9] who documented growing gaps in mortality by socioeconomic status. Such findings are consistent with and may be associated with the increasing gap in life expectancy between the White and Black populations in the period from 1984 through 1989.

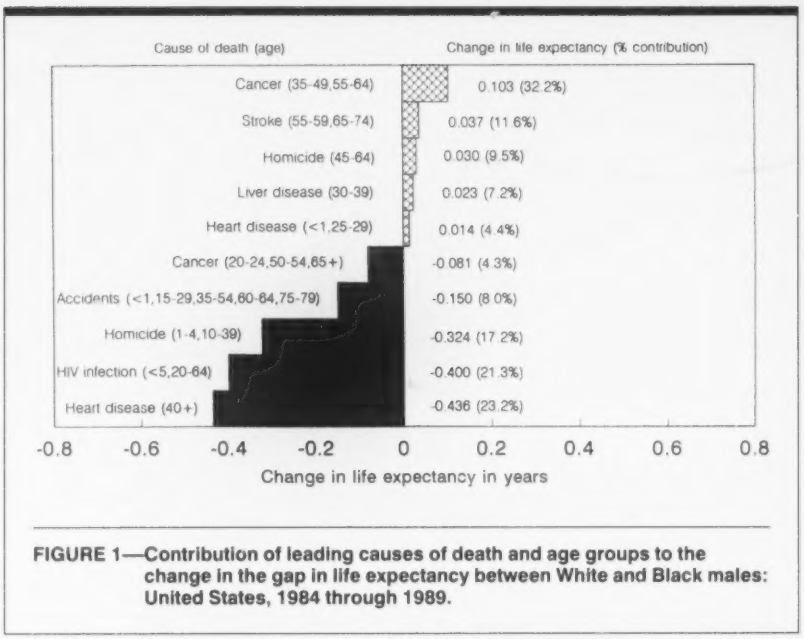

FIGURE 1—Contribution of leading causes of death and age groups to the change in the gap in life expectancy between White and Black males: United States, 1984 through 1989.

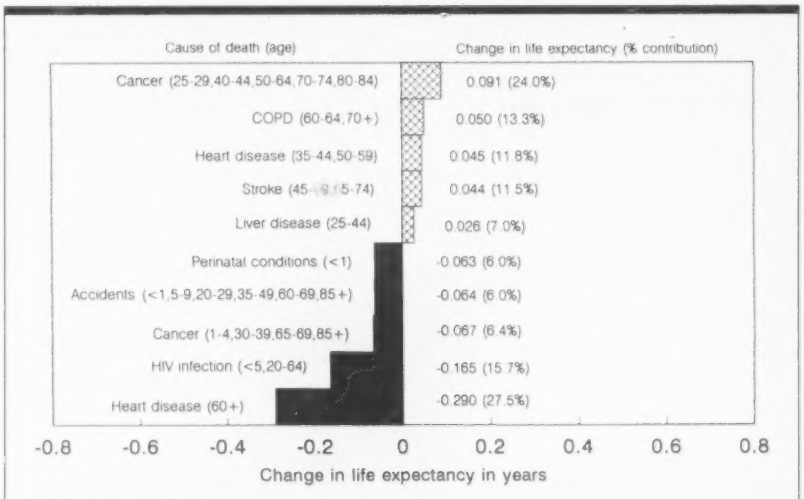

Note. COPD = chronic obstructive pulmonary disease.

FIGURE 2—Contribution of leading causes of death and age groups to the change in the gap in life expectancy between White and Black females: United States, 1984 through 1989.

Some important health problems are shared by all Americans, but for some problems the burden falls more heavily on one racial group than another, on one gender more than the other, and on some age groups more than others. It is clear that not all groups have shared equally in the improvements in health reflected in US mortality statistics, particularly from 1984 through 1989, when the gap in health between our White and Black populations

widened in an unprecedented manner. This analysis identifies the specific ways in which this widening occurred. □

The Effects of Occupational Class Transitions on Hypertension: Racial Disparities among Working-Age Men

ABSTRACT

Objectives. This study was undertaken to examine how the interaction between occupational class transitions and race affects the incidence of hypertension.

Methods. A cohort of 1982 men (183 Black), ages 25 to 55, received a baseline medical exam between 1971 and 1975 and a follow-up between 1982 and 1984. Logistic regressions were estimated for hypertension at follow-up controlling for hypertension at baseline, other risk factors associated with blood pressure, and interaction terms identifying specific occupational class transitions among Blacks and Whites. The occupational class matrix was based largely on scores of US Census Bureau occupations from the *Dictionary of Occupational Titles.*

Results. Relative to Whites who remained in professional and technical jobs between baseline and follow-up, Blacks and Whites who remained in lower occupational classes or made specific transitions—notably into the lowest class—had significantly higher incidence rates of hypertension. These differences were greater among Blacks, who are also more concentrated in and less likely to move upward from the lower end of the occupational class matrix.

Conclusions. Widening racial disparities in high blood pressure over the period of study may be partly attributable to characteristics associated with occupational class position and dynamics. (*Am J Public Health.* 1994;84:945–950)

Norman J. Waitzman, PhD, and Ken R. Smith, PhD

Introduction

Hypertension is a major risk factor for heart disease and stroke.[1] Its higher prevalence among Blacks relative to Whites in the United States is well documented[2–4] although the mechanisms underlying this racial disparity are not fully understood. The distinct income and social class gradients exhibited by blood pressure[3–6] suggest that characteristics associated with the disproportionate concentration of Blacks in poverty and low-paying, insecure jobs are partly responsible.

Several epidemiological studies support the view that psychosocial stress among lower socioeconomic strata contributes to differences in blood pressure,[4,6–9] and a review of the literature suggests that employment security and other work conditions play a pivotal role.[10] The presence of low decision latitude on the job in the face of high demands, a pattern most characteristic of jobs with low social status, has been shown to be directly associated with the risk of cardiovascular disease[11] and elevated blood pressure.[12–14] A separate group of studies on blood pressure by race[7–9] has focused on internalized demands arising from a belief system that has been labeled "active coping" or "John Henryism": the perception that environment can be mastered through individual determination. These studies have generally supported an interactive relationship between John Henryism and low socioeconomic status leading to elevated blood pressure among Blacks[7–9] but not among Whites.[9]

Most of the above research relating psychosocial stress to blood pressure has drawn inferences from cross-sectional data[7–9,12] and has focused on particular subgroups of the population, such as residents of rural, southern communities[7–9]; workers within a very limited number of occupations[13] or occupational strata[7–9]; or a cohort of relatively young workers.[14] The few longitudinal studies that have investigated the association between occupational strain and blood pressure[13–14] are limited with respect to sample size and scope, as noted above, and have not addressed racial differences. Furthermore, none has investigated the experience of social mobility as a potential factor. Some research has suggested that the prospects of upward occupational mobility are greater for Whites than for Blacks.[15]

We performed a longitudinal analysis of occupational class transitions and blood pressure changes among a nationally representative sample of Black and White men in the United States who were followed for 7 to 13 years after receiving a baseline medical examination. Our measures of occupational class were based on characteristics that have distinct similarities to the demand/latitude characteristics in earlier research.[11–14] While our data do not permit us to include explicit measures of active coping in our model, some of the significant correlates of John Henryism in earlier studies, such as education and occupational status, figure into our classification scheme.

Methods

Study Sample

The sample consisted of a cohort of Black and White men from the first

National Health and Nutrition Examination Survey (baseline) and the National Health Examination Follow-Up Survey (follow-up) who were aged 25 to 55 at baseline; were neither retired nor unable to work owing to sickness at baseline or follow-up; and had complete blood pressure, occupational, and other covariate data. Men aged 56 or older were excluded from the sample because of their low rates of occupational reporting at follow-up largely owing to retirement. The baseline survey was conducted between 1971 and 1975, and the follow-up was conducted between 1982 and 1984. Of 2666 males at baseline who met the above criteria, 149 died and 218 were otherwise lost to follow-up. Missing data for occupational and other variables were responsible for an additional loss of 317 respondents. Of the remaining 1982 respondents who met all the sample selection criteria, 183 were Black.

The potential for sample selection bias is of particular concern in longitudinal panel studies because those lost to follow-up may differ in some nonrandom way from those who remain in the sample.[16] Sample selection bias in the regressions was formally tested and corrected for, based on the Heckman technique.[16,17] The test suggested the absence of such bias, so results are reported without the sample selection bias correction.

Specification of Variables

The measurement protocol for blood pressure was similar but not identical across surveys. A single measurement according to then-standard guidelines[3] was taken at baseline while three successive measures during a single exam were taken at follow-up. Summary data and regression results reported below use the first reading at follow-up to preserve consistency in measurement across the two surveys. Results from regressions using averages of the second and third readings at follow-up in accordance with current guidelines,[2] however, were nearly identical to those reported here.

Both dichotomous measures of hypertension used in this analysis are based on definitions of the lower bounds for mild hypertension (diastolic ≥ 90 mm Hg) or borderline systolic hypertension (systolic ≥ 140 mm Hg) established by the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure.[2] The second measure also incorporates information on usage of blood pressure medication. Respondents were asked whether they were taking prescribed blood pressure medication at follow-up. Information on such medication at baseline was gathered for a nationally representative subsample comprising two thirds of the baseline respondents, however, and therefore was not used in the analysis to ensure as large a sample as possible. In analyses based on this subsample, such an adjustment made no significant difference in the results.

Respondents were overweight if their body mass index (weight in kilograms/height in meters squared) at baseline equaled or exceeded that of the 85th percentile of the body mass distribution among the adult male population between 1976 and 1980.[18] The variable for daily alcohol consumption was based on self-reports of the amount and frequency of consumption at baseline and was calculated as number of drinks per day $\times$ reported frequency of drinking $\times$ 0.5, with 0.5 being an estimate of the amount of ethanol in a shot of liquor, a 5-oz glass of wine, or a 12-oz glass of beer.[19]

Occupational Classification

Health and labor market studies that use a scheme for occupational status have often relied on census one-digit occupational categories. However, these categories tend to be heterogeneous, give insufficient weight to job content and its changes over time, and lack a consistent base in labor market or social theory.[20,21] Drawing on labor market segmentation theory to overcome these weaknesses,[22,23] this analysis used occupational ratings at the three-digit level for census occupations and incorporated differences in jobs arising from industry characteristics.

According to segmentation theorists, the labor market is roughly split between a primary market in which jobs are relatively secure, pay well, and offer opportunities for training and advancement, and a secondary market characterized by low-paying, dead-end jobs. For this study, a four-part segmentation scheme, which partitions the primary labor market into three segments, was adopted.[23,24] The topmost segment (class 1) comprises technical and professional jobs that require several years of general educational preparation and involve independent decision-making and/or supervisory responsibilities. Jobs in class 2 are craft jobs that require several years of vocational training and also afford latitude in decision making. Occupations in class 3 are more often machine paced and subject to strict timetables, rules, and supervision than are jobs in the upper two classes, but they still offer job security and opportunities for advancement. Such security and opportunities in secondary labor market occupations (class 4) are minimal even though skill requirements may be similar to those for entry-level jobs in class 3.

The four-part segmentation scheme was operationalized on the basis of both scores on educational and training requirements for occupations and ratings on the extent to which jobs afford decision-making latitude or require working at a repetitious or set pace, as per the *Dictionary of Occupational Titles*.[25] Workers could be reassigned between the bottom two classes based on census industrial characteristics. A description of the method is available from another source.*

Occupational Variables

A respondent could be in any of the four occupational classes at baseline and at follow-up, suggesting a 4 $\times$ 4 class transition matrix. Cells along the diagonal of such a matrix identify those who were in the same class in both surveys, whereas off-diagonal cells identify "movers." Because the number of Blacks in the sample in several off-diagonal cells was small, it was not possible to construct variables specifying all 16 occupational transitions by race. Accordingly, certain cells were collapsed for use in subsequent regressions. In particular, the direction of an occupational move (up or down) and the destination (class at follow-up) are the two dimensions used to identify occupational transitions. Destination classes are important because they are more proximal in time to recorded levels of blood pressure at follow-up than are classes of origin. Downward moves may generally be considered more detrimental to health than upward moves.

Dummy variables identify specific transitions that preserve direction and destination for both Whites and Blacks. The variable "Moved down to class 4," for example, identifies downward moves from

class 1, 2, or 3. The "Stayed in class 1, 2, 3, or 4" dummies identify the four groups that did not change occupational class.

The model from which regression results are reported below incorporates interaction terms between race and occupational class transitions. Goodness-of-fit comparisons between logistic regressions based on changes in the likelihood ratio indicate that the interaction terms detected in the final model fit the data better than simpler models. These results suggest that, in addition to theoretical considerations, this is the "best" model on statistical grounds.[26,27]

Model Specification

Logistic regressions were run on two dichotomous measures of hypertension at follow-up. One measure is an indicator of uncontrolled hypertension; the other counts as hypertensive an additional 150 respondents on antihypertensive medication whose blood pressure was controlled at follow-up. The two measures were incorporated to test the extent to which hypertension control through medication was related to occupational class transition.

Use of blood pressure medication at follow-up was incorporated as a separate covariate in the regression on uncontrolled hypertension. In this regression, such medication was expected to have a positive relation to changes in blood pressure, as those who took it would have done so because their blood pressure was increasing. However, among hypertensives at baseline, those taking medication at follow-up were expected to have lower blood pressure than their nonmedicated counterparts. Blood pressure medication was therefore also interacted with the baseline measure of hypertension in this regression, and these expectations were borne out in the results.

The association between occupational class and high blood pressure was expected to follow a general inverse relationship.[3-6] The defining characteristics of the occupational segmentation scheme focused the analysis on underlying mechanisms for this relationship, such as demands imposed by machine pacing and the level of decision-making authority, as suggested by the literature on occupational characteristics and blood pressure.[10,12-14] Staying in or moving into lower rather than higher occupational classes was therefore expected to be associated with the largest increases in blood pressure.

TABLE 1—Sample Distribution by Occupational Class[a] at Baseline and Follow-Up and by Occupational Class Transition, by Race[b]

	Baseline		Follow-Up		Transition	
	White (n = 1799)	Black (n = 183)	White (n = 1799)	Black (n = 183)	White (n = 1799)	Black (n = 183)
Class

Moved up to class						
1	...	...	...	...	189 (10.6)	9 (4.9)
2	...	...	...	...	63 (3.5)	11 (3.8)
3	...	...	...	...	56 (2.6)	15 (8.0)

[a]In general, jobs in class 1 rank high in educational requirements and/or decison-making authority; jobs in class 2 rank high with respect to vocational training; jobs in class 3 rank low with respect to vocational training and/or high in repetitive operations; jobs in class 4 rank very low with respect to training requirements.
[b]Weighted column percentages in parentheses may not add to 100 because of rounding.

The baseline measure of hypertension was incorporated as a covariate in each regression. Other covariates, such as overweight, alcohol intake, baseline age, and aging (the time between baseline and follow-up exams), were incorporated because of their demonstrated association with elevated blood pressure.[2] Population density has an inverse association with measures of blood pressure,[3] perhaps because of better access to medical care or medical information in urbanized areas. Thus, an indicator variable was incorporated for residence in the center city of a standard metropolitan statistical area as a proxy for access to general medical resources.

Results

The distribution of the study sample by occupational class and race at baseline and follow-up reported in the first four columns of Table 1 is similar to that reported in other segmentation studies,[15,24] with Blacks more than Whites being concentrated in the lower reaches of the occupational hierarchy (classes 3 and 4) at both baseline and follow-up. Whites are represented more in professional and technical jobs (class 1).

The distribution of the sample by transition is reported in the final two columns of the table. About two thirds of both Black and White workers remained in the same occupational class between baseline and follow-up while one third moved. Among stayers, however, about half of Blacks stayed in the bottom class while nearly half of Whites remained in the top class. Among those outside the top class at baseline, a greater percentage of Whites than of Blacks moved up, particularly into the top class, whereas among those outside the bottom class, a greater percentage of Blacks than of Whites moved down, particularly into the bottom class. This mobility pattern is consistent with that found in other research.[15]

Age-adjusted means for blood pressure at baseline and follow-up by race and occupational transition are presented in Table 2. The decline in these means

TABLE 2—Mean (Age-Adjusted) Baseline and Follow-Up Blood Pressure, by Occupational Class[a] Transition and Race

[a]In general, jobs in class 1 rank high in educational requirements and/or decison-making authority; jobs in class 2 rank high with respect to vocational training; jobs in class 3 rank low with respect to vocational training and/or high in repetitive operations; jobs in class 4 rank very low with respect to training requirements.
[b]Only one case in this category.

between baseline and follow-up for several of the transitions for both races reflects, to a certain extent, the greater use of blood pressure medication at follow-up (about 16%) than at baseline (about 3% based on a two-thirds random sample).

Odds ratios and 95% confidence intervals from the logistic regressions on hypertension for the variables identifying class and race interactions are reported in Table 3. The reference category is "stayed in class 1" among Whites. Results from equation 1 indicate that Whites and Blacks who stayed in class 3 or 4 had a greater risk of developing uncontrolled hypertension than did Whites remaining in class 1, although the odds ratios for Blacks were more than twice that of their White counterparts. An even more profound difference surfaced for Blacks remaining in class 2, although the generally wider confidence intervals on results for Blacks, reflecting smaller numbers, are particularly pronounced for this transition. Blacks remaining in class 1 did not exhibit a significant difference from their White counterparts.

Among those experiencing occupational class transitions, downward movement into the bottommost class was associated with significantly higher odds of uncontrolled hypertension among Blacks. The relative risk was also significantly higher for certain upward transitions, most notably among Blacks moving from class 4 to class 3.

Results (not shown) on a measure of more severe uncontrolled hypertension (follow-up diastolic ≥ 105 mm Hg or follow-up systolic ≥ 160 mm Hg) indicated that the odds ratios for the above patterns were generally enhanced among both Blacks and Whites. The relative risks of this more severe hypertension for Whites remaining in each of the bottom two classes, for example, were larger and statistically significant ($P < .02$). The odds ratios for Whites experiencing downward moves into the bottom two classes were also significant for this measure, whereas none of the odds ratios on upward moves among Whites was significant.

Results on the measure of controlled or uncontrolled hypertension are similar to those for uncontrolled hypertension (Table 3). However, the higher odds ratios for Blacks moving into the top class and for those remaining there suggest that these groups may have had better access to medication, adhered more strictly to a medication regimen, or experienced greater efficacy from such medication than did their counterparts experiencing other transitions.

Discussion

Our findings indicate that the incidence of high blood pressure was significantly associated with occupational class position and transition among both Black and White men. The relative risk of hypertension was generally higher among Blacks and among occupational cells near the bottom of the occupational hierarchy where Blacks are most highly concentrated (stayed in class 3 or 4, or moved up to class 3).

The absence of a significant difference among Blacks remaining in the top class calls into question a general relative increase in hypertension by race. Such a conclusion is provocative but preliminary, given the small number of Blacks in this cell. The significant racial differences in hypertension by other occupational class transitions may be related to differences in jobs held by Blacks versus Whites within a given class. An inspection of three-digit census occupations held by race among those remaining in class 2, where the most profound difference in hypertension by race surfaced, failed to indicate obvious differences in occupational patterns for this particular transition. The fact that Whites in the sample more readily experienced upward transitions than did Blacks, however, suggests that the prospect for advancement may be an implicit characteristic that differentiates jobs by race but is not sufficiently captured by the segmentation scheme.

It is also possible that there are unmeasured characteristics of individuals within occupations that could also be responsible for the differences in incidence of hypertension by race. Lower educational level among Blacks, for example, could be a risk factor in hypertension because of education's relationship to higher levels of active coping and because education itself constitutes a resource for coping.[7] The incorporation of measures of education into our analysis, however, did not significantly alter our reported results.

The period covered by this study is widely recognized as one of intense industrial and occupational restructuring in the United States.[28-32] Some of the noted features of this restructuring are captured to some degree as vertical moves from class 2 or 3 to class 4. But several economists have noted that another fundamental aspect of industrial restructuring

during the period, particularly within the craft and manufacturing sectors, has been horizontal segmentation—the downgrading through lower pay, benefits, or job security of what were heretofore "good" jobs, due in part to the intensification of international competition and the decline in union strength in these sectors.[28,30,31] Such horizontal transformations may not be captured in our occupational class matrix. Yet some of the significant results in the regressions for remaining or moving into or out of classes 2 and 3, particularly among Blacks, could reflect such changes.

Wilson has also cited the loss of unskilled and semiskilled manufacturing jobs as a major contributor to the intensification of poverty among Blacks over the period of our analysis, especially in urban centers.[32] The significant results for remaining in or moving into class 4 occupations, highest among Blacks, are likely to capture some effects related to the Wilson hypothesis. We incorporated measures of poverty into our regressions (not shown) to test the extent to which the uncovered differences in hypertension by occupational class and race might be attributable to extreme financial hardship. None of these measures, however, proved to be significant.

Comparative results on the two measures of hypertension suggest that access to, usage of, or the efficacy of antihypertensive medication might be a factor in the uncovered racial differentials in hypertension by occupational class. The precise role that such access or use might play needs to be examined more closely with richer data than were available for this study.

Our analysis is based on blood pressure readings taken at two points in time that spanned several years. While more blood pressure measurements would have been useful, we feel that this cohort study is an improvement over the largely cross-sectional literature relating blood pressure to socioeconomic status.[3-9] To the extent that blood pressure measures at baseline already reflect the effects of occupational class position and transition (see Table 2), our results may understate the full impact of such effects, not only because we adjust for baseline measures of blood pressure but also because we control for other factors related to blood pressure, such as obesity, that have also exhibited social class gradients in other studies.[10,33]

Our use of occupational characteristics as a basis for social stratification has several strengths. The isolation of specific job attributes, such as repetitious tasks and the absence of decision-making authority, that underlie our stratification scheme as potential risk factors for high blood pressure provides a concrete direction for public health policy regarding the design of work. Occupational transitions are also an important basis for changes in income and social status in adult life, whereas other measures of socioeconomic status, such as education, are relatively stationary. Our results relating to both remaining in and moving into jobs where opportunities for training and advancement are typically constrained suggest that reduced prospects for vocational training and occupational mobility may play a formidable role in the incidence of hypertension and may be an important factor in racial differences in hypertension and, by extension, in the incidence of heart disease.

[a]In general, jobs in class 1 rank high in educational requirements and/or decision-making authority; jobs in class 2 rank high with respect to vocational training; jobs in class 3 rank low with respect to vocational training and/or high in repetitive operations; jobs in class 4 rank very low with respect to training requirements.

[b]Odds ratios were derived from logistic regression models that also included age, aging between baseline and follow-up exams, body mass index, alcohol use, urban residence, hypertension, and, for equation 1, use of blood pressure medication at follow-up. All covariate measurements were taken at baseline unless otherwise noted.

[c]Follow-up systolic ≥ 140 mm Hg or diastolic ≥ 90 mm Hg.

[d]Only one case in this category.

[e]Follow-up systolic ≥ 140 mm Hg or diastolic ≥ 90 mm Hg or respondent takes blood pressure medication at follow-up.

To reduce racial disparities in high blood pressure and associated disease and mortality is a prominent public health goal of the nation.[1] While the Public Health Service has specifically singled out the work site as a valuable arena for blood pressure screening, education, referral, and control activities,[1] our findings suggest that certain structural aspects of work also merit attention with respect to these goals. □

Diagnoses, Symptoms, and Attribution of Symptoms among Black and White Inpatients Admitted for Coronary Heart Disease

James M. Raczynski, PhD, Herman Taylor, MD, Gary Cutter, PhD, Michael Hardin, PhD, Neil Rappaport, PhD, and Albert Oberman, MD, MPH

ABSTRACT

Objectives. This study examined health care–seeking behaviors to elucidate factors that contribute to differences in patterns of coronary heart disease between African Americans and Whites. The prevalence of diagnosed coronary heart disease, patients' perceptions of symptoms and attribution of symptoms, and predictors of painful symptoms and attribution of cardiac symptoms were examined.

Methods. The study involved 2416 patients admitted with diagnoses of coronary artery disease, ischemic heart disease, or myocardial infarction or to rule out myocardial infarction. Structured interview questions were used to obtain demographic information, symptoms precipitating admission, and patients' attribution of their symptoms. Discharge diagnoses were obtained from hospital records.

Results. Acute myocardial infarction, unstable angina, nonacute ischemic heart disease, and atherosclerosis were more frequent in White patients. For Blacks, the odds of reporting painful symptoms were only 64% of the odds found for Whites when other factors were controlled, and the odds of attributing symptoms to cardiac origins were almost 50% lower for Blacks than for Whites.

Conclusions. The tendency of Blacks to report fewer painful symptoms and to attribute their symptoms to noncardiac origins may contribute to differences in care-seeking and in medical management of heart disease in Blacks. (*Am J Public Health.* 1994;84:951–956)

Introduction

Coronary heart disease mortality rates for Blacks exceed those of Whites for persons aged 25 through 64 years.[1–4] These differences have led working groups[5] and others[2,3] to call for investigations of factors affecting coronary heart disease in Blacks, particularly individual and environmental factors related to patterns of coronary heart disease that affect care-seeking behavior.[6–9] Prominent among factors hypothesized to affect health care–seeking behavior are the patient's perception of symptoms and attributions made concerning the cause of these symptoms.[10]

As part of a larger project that addresses differences between Black and White patients and community respondents in seeking health care for coronary heart disease (the Birmingham–Black Health Seeking for Coronary Heart Disease Project), we interviewed patients who had been admitted to the hospital for known or suspected cardiac events. The purpose of this paper is to describe the symptoms that were reported by these patients, the frequency of coronary heart disease diagnoses, and relationships between these symptoms and patients' attribution of symptoms.

Methods

Patient Selection

In 1989 and 1990, hospital inpatients were interviewed in three counties in Alabama: Jefferson County, within which Birmingham is located; St. Clair County; and Talladega County. Patients were recruited from five hospitals located in these counties: the University of Alabama Hospital, a large teaching hospital in Birmingham; the Department of Veterans Affairs Medical Center in Birmingham; Cooper Green Hospital, a county hospital for the medically indigent in Birmingham; St. Clair County Hospital, a private hospital serving a rural county; and Coosa Valley Hospital, a private hospital located in Talledega County, also a rural county. Patients approached for interview were those diagnosed with coronary artery disease, ischemic heart disease, chest pain, or myocardial infarction or those admitted to rule out myocardial infarction. Only patients who identified themselves as White or Black completed interviews. Of the patients who were approached, 31 (1.3% of the final sample) refused to be interviewed, and 156 patients terminated the interview prior to completion for various reasons. Of the patients approached, 92.3% completed the interview. The number of participants interviewed was as follows: 1140 White men, 347 Black men, 574 White women, and 355 Black women.

Interview and Data Collection Methods

All interviews were conducted by trained and certified interviewers who underwent periodic retraining to ensure consistency in interview methods. Re-

Particular usual care facility, %	88.4	79.9	< .001	89.9	81.1	< .001
Privately insured, %	44.1	35.1	.003	29.0	17.1	< .001
Medicaid insured, %	3.0	10.1	< .001	10.4	24.3	< .001
Medicare insured %	32.2	26.7	.054	31.7	35.1	.277

Note. CHD = coronary heart disease.

search interviews were conducted in the rooms of willing hospital inpatients. The interviews asked for demographic information, the symptoms that precipitated admission, and attributions for these symptoms at the time they occurred. In addition to the structured interview, discharge diagnoses were obtained from hospital medical records.

Statistical Analyses

Participants were stratified by sex and initial comparisons were conducted for key demographic characteristics between races. Chi-square analyses were used to address differences between racial groups in the frequency distributions obtained from demographic and other key questionnaire items. Frequencies of diagnostic category groupings were compared for racial groups. Perceived symptoms and attributions of symptoms were then examined for differences between Blacks and Whites by sex with chi-square analyses. To ensure that results were similar for the entire patient sample and patients with definite coronary heart disease (*International Classification of Diseases*, ninth revision[11] [ICD-9] diagnoses 410–414), analyses were completed for both sets of patients. Because chest pain is the primary symptom associated with coronary heart disease and either chest pain or pain in other areas might motivate patients to seek treatment, we were interested in assessing the factors that were associated with painful symptoms and attribution of symptoms to cardiac origins. Attribution of symptoms was thus examined for the entire patient sample. Multiple logistic regression analyses were used to examine the relationship of selected demographic characteristics to painful symptoms and attribution of symptoms to cardiac origins. Like the symptom and attribution analyses, these multiple logistic regression analyses were completed both for the entire patient sample and separately for the patients with coronary heart disease (ICD-9 diagnoses 410–414) and those in other diagnostic groups.

Results

Participant Characteristics

Characteristics of respondents are summarized in Table 1. A total of 1487 men (1140 Whites and 347 Blacks) and 929 women (574 Whites and 355 Blacks) were interviewed. Of the entire sample, 29.1% were Black and 38.5% were women. While the ratio of White male inpatients to White female inpatients was almost 2 to 1, the numbers of black Male and Female inpatients were comparable. White participants were older and more educated than their Black counterparts. Fewer Blacks than Whites were married or living as married. Comparable numbers of Whites and Blacks within each sex group reported working full or part time. Differences between the racial groups emerged in self-reported risk factors. Hypertension was reported almost twice as often by Black respondents as by Whites. A higher percentage of White than Black men smoked, and more Whites than Blacks of both sexes reported being hypercholesterolemic. Diabetes was reported very infrequently in all groups. More White than Black respondents reported a positive family history of heart disease. Comparable percentages of Black and White women reported having a history of a coronary heart disease diagnosis, but a lower percentage of Black men than White men reported a previous coronary heart disease diagnosis. Although more than 80% of the entire sample reported having a usual source of care, more Whites than Blacks reported having a usual care source. A higher percentage of White than Black respondents were covered by private insurance, although less than half of the entire sample (less than a third for women) was privately insured. Medicaid coverage was greater among both Black men and women than among Whites. However, despite the Medicare and Medicaid coverage, approximately twice as many Blacks as Whites were uninsured.

Frequency of Coronary Heart Disease Diagnoses

Table 2 summarizes the frequency of discharge diagnoses by sex and racial groups. White men and women were more likely than their Black counterparts to have diagnoses of acute myocardial infarction and unstable angina (ICD-9 diagnoses 410–411) and nonacute ischemic heart disease and atherosclerosis (ICD-9 diagnoses 412–414). Black men and women were more likely than Whites to have other forms of heart disease (ICD-9 diagnoses 420–429) and to not have any cardiac diagnosis.

Symptom Perception and Attribution

Table 3 describes the symptoms that precipitated hospital admission for the entire sample of patients and for those patients who had diagnoses of myocardial infarction, ischemic heart disease, or

atherosclerosis (ICD-9 diagnoses 410–414). In the entire sample, Whites reported more arm pain and numbness than Blacks. When all painful symptom categories were collapsed to examine patients who reported any painful symptom, White men were found to report more overall painful symptoms than Black men (75% vs 68%). The data for women showed similar trends (76% vs 70%), suggesting that White women also experienced more painful symptoms than their Black counterparts. The number of patients reporting any nonpainful symptom, obtained from collapsing across all nonpainful symptom categories, revealed that Blacks reported more nonpainful symptoms than Whites. Restricting the analysis to patients with coronary heart disease diagnoses revealed somewhat different results. More than twice as many White men as Black men reported arm pain and numbness. There were no differences in painful symptom reports between racial groups for women, and neither sex showed differences between racial groups when all of the painful symptom categories were collapsed. Black female coronary heart disease patients reported more overall nonpainful symptoms than did White female coronary heart disease patients, as was true for the entire patient sample, but men reported no overall differences in nonpainful symptoms. Very few patients reported no symptoms associated with their admission.

Table 4 displays the initial attributions that patients made for their symptoms. About one quarter of the White men in the entire sample attributed their symptoms to heart attack and one quarter to angina, and these proportions remained when only the coronary heart disease patients were considered. However, fewer Black men in the entire patient sample attributed their symptoms to heart attack, and fewer Black men in both patient groups thought that their symptoms were due to angina. In the entire patient sample, but not in the coronary heart disease patient sample, Black men were more likely than Whites to attribute symptoms to causes that are not listed in Table 4. For women in the entire patient sample, differences between racial groups in attribution of symptoms to myocardial infarction and angina were similar to those found for the men. However, Black and White women in the coronary heart disease sample did not differ in their attribution of symptoms to myocardial infarction and angina.

We also examined separately the attributions made by those patients who reported having chest pain as a symptom, and the findings were very similar to those for the entire patient sample. Black patients were less likely than Whites to attribute their chest pain to cardiac origins (40.9% vs 61.0% for Black and White men, respectively, $P < .001$; 48.7% vs 57.7% for Black and White women, respectively, $P = .028$). Attribution of chest pain symptoms to indigestion, heartburn, or stomach or esophageal problems was also more common among Black than

Predictors of Chest Pain and Attribution of Symptoms to Cardiac Origins

Results of the multiple logistic regression analyses for predictors of painful symptoms and attribution of symptoms to cardiac origins are summarized in Table 5. Factors associated with the report of painful symptoms were being White, having a coronary heart disease diagnosis, smoking, not having a positive family history of coronary heart disease, having a particular usual care facility, having private insurance, and having Medicare insurance. To examine further the influence of diagnosis on painful symptom prediction, we conducted additional multiple logistic regression analyses with different diagnostic group classifications (ICD-9 diagnoses 410–411 and 410–429) coded in the coronary heart disease diagnosis variable of our model. The results of these analyses confirm the significant independent contributions of race and having a particular usual care facility.

Factors associated with attributing symptoms to cardiac origins were being White, having a coronary heart disease diagnosis, being more educated, having previously been diagnosed as having coronary heart disease, and having a particular usual care facility. Repeated analyses with our different diagnostic group classifications (ICD-9 diagnoses 410–411 and 410–429) coded in the coronary heart disease diagnosis variable of our model similarly suggested that race is an independent predictor of attribution of symptoms to coronary heart disease origins.

Discussion

The experience of painful symptoms and the attribution of symptoms to cardiac origins are two factors that presumably affect treatment seeking and possibly influence medical management. As in previous studies,[12,13] the African-American patients in our sample were younger than the White patients. Self-reported risk factor differences emerged between Whites and Blacks in our sample. Black men and women were twice as likely as their White counterparts to be hypertensive. Whites reported higher rates of hypercholesterolemia and family history of heart disease. Differences in access to

care also emerged between racial groups. More Whites than Blacks reported that they had a particular source of usual care. The economic advantage of the White patients was also reflected in rates of insurance coverage.

We found that Whites were more likely to have discharge diagnoses of acute myocardial infarction and unstable angina (ICD-9 diagnoses 410–411) and nonacute ischemic heart disease and atherosclerosis (ICD-9 diagnoses 412–414) and that Blacks were more likely to have discharge diagnoses of other forms of heart disease (ICD-9 diagnoses 420–429) and not to have cardiac diagnoses. This finding that coronary heart disease is less common among Blacks than whites, at least among those seen as inpatients, is similar to findings from the Coronary Artery Surgery Study[14] and the Myocardial Infarction Triage and Intervention study.[12]

Symptoms associated with hospital admission also differed between Whites and Blacks. In our overall patient sample, Whites of both sexes reported experiencing slightly more arm pain and numbness than did Blacks. Overall, White men reported more painful symptoms than Black men. More nonpainful symptoms were reported by Blacks than Whites of both sexes. Thus, the symptom patterns of Whites and Blacks seem to differ in a sample of patients admitted for suspected coronary heart disease. Although similar percentages of Whites and Blacks within each sex group experienced the primary symptom of heart disease, that is, chest pain or discomfort, the overall symptom pattern suggests that more nonpainful symptoms may be reported by Blacks than by Whites. The effect of these nonpainful symptom reports on medical decision making is not addressed by our data; however, one might speculate that patients' reports of painful symptoms would influence medical decision making to at least some degree. Conversely, the lack of classic symptoms can also affect medical decision making and the diagnostic workup.

Restricting our symptom analysis to patients with acute diagnoses of coronary heart disease (ICD-9 diagnoses 410–414) produced somewhat different results. Generally, both Blacks and Whites with coronary heart disease reported similar symptoms, although some differences persisted. Significantly fewer painful symptoms and more nonpainful symptoms were reported by Black patients.

In addition to differences between Whites and Blacks in the perception of symptoms, we found differences in attribution of symptoms. Approximately half of the White men and women in our overall patient sample had attributed their symptoms to cardiac origins, whereas fewer than one third of Black men and slightly more than one third of Black women had thought that their symptoms were related to their hearts. Correspondingly, Blacks were more likely to attribute their symptoms to a host of other origins. Restricting our analysis to patients with acute coronary heart disease diagnoses revealed similar differences in attribution for male patients; for women, however, the pattern of symptom attribution was similar for Blacks and Whites. Analyses of data for only those patients who reported chest pain showed that again, Blacks less commonly attributed their symptoms to cardiac origins and more commonly attributed them to noncardiac origins. These differences in attribution may influence the care-seeking behavior of patients, which, in turn, may influence medical decision making that is associated with patients' perceptions of their symptoms. Since the patients we studied are the patients who made it to the hospital, several key questions remain. In addition to the selective nature of our inpatient sample, selective attrition due to factors such as sudden death may have biased our results.

As the results of the multiple logistic regression analyses emphasize, race was independently associated with both perception of painful symptoms and attribution of symptoms to cardiac origins. For Blacks, the odds of reporting painful symptoms were only 64% of the odds found for Whites when other factors were controlled, and the odds of attributing symptoms to cardiac origins were almost 50% lower for Blacks than for Whites. It is possible that ethnic background may account for differences in symptom perception and attribution in a number of different ways. First, it may be that there are physiological mechanisms that result in lower rates of perceived pain. Second, cultural and ethnic background may be associated with pain tolerance.[13] Berkanovic and Telesky suggest that a historical stoic response to illness may persist among Blacks.[15] This and other cultural factors may affect the perception of symptoms.[16] Finally, reports indicate that Blacks are less knowledgeable than Whites about heart disease symptoms,[17] suggesting that they may be less aware of heart disease, less alert to painful symptoms, and less likely to attribute symptoms to cardiac origins. Alternatively, these reports may reflect differences between Blacks and Whites in the presentation of cardiac disease.

In addition to race, our multiple logistic regression analyses found other variables that were associated with painful symptoms. The association of diagnosis with painful symptom reports is as might be predicted: patients with coronary heart disease discharge diagnoses were more likely to report painful symptoms. Several other relationships also emerged, although these relationships were not consistent across models. Smoking was the only risk factor associated with painful symptom reports, and having a family history of heart disease was associated with not having painful symptoms. Having a particular usual care facility was associated with having painful symptoms in all of the multiple logistic regression analyses. Whether or not a person has a particular usual care facility would not seem to directly affect the experience of cardiac symptoms, although it is possible that persons who have more overt symptoms, including pain, are more likely to seek out a usual care provider. Alternatively and perhaps more likely, it may be that persons who seek primary care are those who do not deny their symptoms and are therefore more likely to report painful symptoms when they occur. Patients with private insurance and Medicare insurance were more likely than their uninsured counterparts to have painful symptoms, again possibly reflecting either the seeking of insurance coverage for those experiencing pain or less denial about pain among those privately insured.

Like reports of painful symptoms, diagnosis was associated with attribution of symptoms to cardiac origins. As one might expect, patients with coronary heart disease diagnoses, whether at discharge or prior to admission, were more likely to attribute symptoms to cardiac origins. Patients with more education were more likely to attribute their symptoms to cardiac origins, perhaps reflecting more knowledge about what symptoms are associated with coronary heart disease or a greater willingness to accept the possibility that they have coronary heart disease. Having a particular usual care facility was also associated with attribution of symptoms, perhaps for the same reasons that it is related to reporting painful symptoms.

It should be noted that there are several limitations in our data and the inferences that can be made from them. The methods that we used resulted in our

examining inpatients who not only had made it to treatment but who were admitted and then stabilized, thus excluding those who never made it to treatment or who were turned away from treatment. The cross-sectional design also limits the causal inferences that can be made. The reliance on self-report data, with their inherent biases, is also a limitation. Severity of symptoms and comorbidity may be related to symptom patterns and attribution, but these factors were not examined. Finally, these data were obtained largely from patients who reside in Alabama, and the generalizability of the findings to patients from other regions may be limited.

Despite these limitations, our results suggest that among our sample of patients who sought and were admitted for treatment, race was independently associated with both perception of painful symptoms and attribution of symptoms to cardiac origins. When factors other than race were controlled, African-American patients were less likely than Whites to report either experiencing painful symptoms or attributing their symptoms to cardiac origins. While cultural factors and physiological mechanisms may account for these differences in perception, knowledge about symptoms of coronary heart disease may also account for our findings. Lowered awareness of coronary heart disease and its symptoms might be expected to lead to less alertness to painful symptoms and less likelihood of attributing symptoms to cardiac origins. If this proves to be the case, as has been suggested by preliminary reports,[18,19] then educational interventions may be indicated for overcoming these discrepancies. In addition, these findings may suggest that health care providers should be educated about racial differences in symptom perception and attribution. □

Do Blacks and Whites Differ in Their Use of Health Care for Symptoms of Coronary Heart Disease?

Sybil L. Crawford, PhD, Sarah A. McGraw, PhD, Kevin W. Smith, MA, John B. McKinlay, PhD, and Judith E. Pierson, MSW

ABSTRACT

Objectives. The purpose of this study was to identify the role of race in seeking and receipt of care for symptoms of coronary heart disease.

Methods. Data on medical care, sociodemographic characteristics, symptoms, risk factors, income, and insurance were collected in a telephone interview for a random sample of 2030 Black and White adults in inner-city Boston. Rates of care-seeking for symptoms, amounts of delay in seeking care, and rates of receipt of care were compared for Blacks and Whites after adjustment for other characteristics.

Results. Before and after adjustment for other factors, Blacks and Whites were equally likely to seek care. Average delay time was shorter for Blacks, particularly Black women. With the exception of a lower rate of referral to cardiologists among Blacks, receipt of care was similar for Blacks and Whites who sought medical attention for symptoms.

Conclusions. In an urban population of Blacks and Whites who were similar in socioeconomic status and access to medical care, there were few racial differences in coronary heart disease–related care patterns. (*Am J Public Health.* 1994;84:957–964)

Introduction

Recent research suggests that Blacks are less likely than Whites to seek and to receive appropriate medical care for coronary heart disease, the leading cause of death in US Blacks.[1,2] In the Edgecombe County Study, nearly half of all Blacks with repeated chest pain never discussed this pain with a doctor, compared with 27% of Whites.[3] In another study, Blacks admitted to a municipal hospital with documented acute myocardial infarction had waited almost twice as long as Whites before seeking medical care.[4] Other research suggests that Blacks make less use of ambulatory care, including office visits for coronary heart disease and other circulatory system diseases.[5–8] Additional work indicates that Blacks seeking medical care related to coronary heart disease receive lower levels of treatment such as coronary angiography or coronary artery bypass grafting, even after disease severity is controlled,[9–14] and that they receive fewer general and coronary heart disease–related diagnostic and treatment services.[15,16]

Differences in coronary heart disease–related health care use may account for the observed similar or lower prevalence of coronary heart disease[17–19] but higher case-fatality rates and excess mortality[19–27] in Blacks than in Whites. Delays in seeking care, which are negatively associated with prognosis and survival,[4,28,29] could contribute to higher mortality among Blacks with coronary heart disease. Alternatively, reported incidence and prevalence rates, which are often derived from hospital discharge records rather than from population-based studies, may reflect underdetection of coronary heart disease among Blacks owing to their lower rates of help-seeking.[1] Lower levels of care received by Blacks could contribute to both underdetection of coronary heart disease and a higher mortality rate.

These hypotheses underscore the importance of population-based samples, since studies based on unrepresentative samples (e.g., hospital discharge records) can miss persons with coronary heart disease who are not in the medical care system, who may be disproportionately Black. Moreover, non–population-based samples may lead to a biased assessment of help-seeking and care patterns. For example, one study of delay based on hospitalized patients excluded subjects who failed to reach the hospital, some of whom may have been sudden deaths who did not delay in seeking medical assistance.[4] In addition, if Blacks who seek care are less likely than Whites to receive assistance, estimates of rates of help-seeking by Blacks based on hospital or other medical records will be too low, and lower levels of receipt of care in Blacks may be attributed incorrectly to failure to seek care. Thus population-based sampling is critical in studying racial differences in various stages of health care patterns.

A complete assessment of racial differences in utilization or receipt of health care involves identifying not only the extent of such differences, but their sources as well. That is, if there are Black–White differences in patterns of

care, can they be explained by factors related to race? For example, past studies have found that income and insurance coverage explained racial differences in care received.[15,30] Thus racial differences in coronary heart disease–related care patterns may be due in large part to factors related to race, such as socioeconomic status (SES), rather than to race per se.

This study examined patterns of coronary heart disease-related care in a community-based random sample of Black and White adults with similar levels of SES and geographic access to care. First, racial differences in care-seeking in response to coronary heart disease symptoms, both in whether care was sought and in the amount of delay, were assessed before and after controlling for other factors. Second, among those who sought medical assistance, the extent of unadjusted and adjusted racial differences in care received were identified.

Methods

Subject Selection

Data were from a random-digit-dialed telephone survey conducted in three inner-city Boston neighborhoods. The sample was drawn from the community rather than from hospital discharge records to include persons not in regular contact with the health care system. The study's target area consisted of seven zip codes encompassing the Dorchester, Roxbury, and Mattapan neighborhoods. These neighborhoods were selected for their relative homogeneity of household income and geographic access to care, with four major hospitals within the study boundaries and five teaching hospitals bordering the study area. Study respondents were identified through random-digit dialing in the 11 telephone exchanges serving the target area. The same number of dialings was made in each exchange to ensure that all households with telephones in the area had the same probability of being contacted. Eligibility for the study was restricted to Black and White adults born in the United States who were aged 44 to 75 years at the time of the interview. All eligible adults in a household were asked to complete a telephone interview approximately 20 minutes in length. Interviews were conducted between September 1988 and December 1989.

Outcome Measures

Respondents were asked about occurrence of the following coronary heart disease–related symptoms: chest pain, discomfort, pressure, or heaviness, collectively referred to below as "chest pain," and shortness of breath. For the purposes of this study, subjects who reported *ever* experiencing one or more of these symptoms were considered to be symptomatic. Subjects reporting a symptom were asked if they had ever seen a physician or other health care professional in response to the symptom, and if so, the time between first noticing the symptom and contacting the health care professional. Symptomatic respondents who reported ever contacting a medical person in response to chest pain or shortness of breath were considered to have sought help. Delay in help-seeking, measured separately for chest pain and shortness of breath, was defined as the amount of time (in hours) between the onset of the symptom and contact with a medical person. Receipt of care involved eight types of coronary heart disease–related care in three areas: (1) physician-recommended diagnostic procedures: electrocardiogram, treadmill or bicycle exercise test, and echocardiogram; (2) treatment: physician-recommended invasive procedures (coronary artery bypass grafting, angioplasty, and cardiac catheterization), current cardiovascular medication, and hospitalization for myocardial infarction; and (3) other coronary heart disease–related contacts with the health care system: referral to a cardiologist and diagnosis of a heart problem (large heart, heart disease, heart valve problem or heart murmur as an adult, and angina or hardening of the arteries).

Predictor Measures

Predictor information included the following sociodemographic characteristics: race, sex, age, and living situation (with someone or alone). SES measures included high school completion; amount of difficulty in paying for basic necessities, including health care; and current employment status. Respondents were asked about coverage by private insurance, Medicaid, and Medicare. Coronary heart disease risk factors included diabetes, family history of heart disease or stroke, smoking status (current, stopped in past 10 years, never smoked/stopped over 10 years ago), body mass index, diagnosed hypertension, and diagnosed elevated cholesterol. The severity of coronary heart disease symptoms at the time of first occurrence was also noted. Questions about access to and satisfaction with the medical care system were adapted from items used in previous studies of help-seeking[3,31] and included having a usual source of care other than a hospital emergency room, travel time to usual care source, amount of difficulty in traveling to care, level of satisfaction with the amount of time spent with the doctor, level of satisfaction with care received, and need for care not being received. General propensity to seek care was assessed by asking whether the respondent would seek help for six conditions: swelling of the ankles, chronic fatigue, shortness of breath, fainting spells, chest pain, and persistent coughing.[32] Myocardial infarction symptom knowledge was defined as the number of symptoms mentioned in free recall, including chest pain, arm pain, shortness of breath, sweating, nausea, fatigue, dizziness, fainting, and loss of consciousness.

Statistical Analyses

Predictors of help-seeking in response to chest pain were identified by estimating a multivariate logistic regression model for the probability of seeking care by subjects with chest pain. A corresponding model was estimated for the probability of seeking care for shortness of breath by subjects with shortness of breath. For subjects who sought care for chest pain, a multivariate linear regression model was estimated for the amount of delay in seeking care. A similar model was estimated for delay in help-seeking for shortness of breath. Because hours of delay was highly skewed for both symptoms, a log transformation was applied.[33] For receipt of care by symptomatic persons who sought help, separate logistic regression models were estimated for each of the eight types of care. Unadjusted racial differences for each of the outcomes were assessed by including only race as a predictor. Corresponding adjusted racial differences were obtained by adding the remaining predictors. For ease of interpretation, nonoverlapping insurance categories were defined as any private insurance, any Medicare without private insurance, Medicaid only, and uninsured. Because previous analyses of coronary heart disease incidence[1,34] and help-seeking[3] indicated that racial differences vary by sex, the interaction between race and sex was included as a predictor.

Stepwise and backward elimination procedures[33,35] (with $P \leq .05$) were employed to eliminate redundant or unre-

lated covariates from the multivariate models in order to better estimate the effects of the remaining predictors. Model fit was assessed with the Hosmer-Lemeshow statistic[36] for logistic regression models and residual diagnostics for the linear regressions.[33] Computations were performed with SAS[37] and BMDP[38] software. Potential nonresponse bias was examined by comparing study respondents and nonrespondents with regard to demographic characteristics from the household screening. The effect on standard errors of clustering of respondents within households was assessed by calculating design effects for each outcome.[39]

Results

Participants

Random-digit dialing in the target area exchanges identified 2310 adults meeting the study's eligibility criteria. Eligibility status could not be determined for an additional 545 persons who did not complete an individual screening. Telephone interviews were successfully completed with 1222 Black and 808 White respondents (overall response rate = 87.9% among known eligible persons). Of the eligible persons who were not interviewed, 232 refused to participate and 48 could not be recontacted after the initial screening. Because the composition of the respondent sample (39.8% White, 37.8% male) differed very little from that of the full potential sample of 2310 persons (41.2% White, 39.2% male), no adjustments were made for nonresponse. Estimated design effects were very close to 1.00 (ranging from 0.99 to 1.06), indicating that adjustment for household clustering was not necessary.

Of the respondents, 627 Blacks (51.3%) and 380 Whites (47.0%) reported ever experiencing at least one coronary heart disease symptom. Although household income was generally low, Blacks tended to have lower levels of SES than Whites, as seen in education, difficulty in paying for basic necessities, and insurance coverage (Table 1). Blacks had higher rates of diabetes and hypertension but a lower rate of family history of coronary heart disease. Body mass index was slightly lower on average in Whites. The two groups were similar in perceived seriousness of symptoms. With the exception of longer travel times for Blacks, access and satisfaction with care were similar in the two groups. Blacks had a higher propensity to seek care, whereas Whites' knowledge of myocardial infarction symptoms was slightly higher.

Help-Seeking in Response to Coronary Heart Disease Symptoms

There were no racial differences in rates of help-seeking for chest pain or shortness of breath for either sex. The unadjusted odds ratio for Black men vs White men was 0.69 (95% confidence interval [CI] = 0.42, 1.14) for chest pain subjects and 1.08 (95% CI = 0.64, 1.81) for shortness of breath subjects. The corresponding odds ratios for women were 1.12 (95% CI = 0.74, 1.72) and 1.28 (95% CI = 0.82, 2.00). Adjusted racial

Note. OR = odds ratio; CI = confidence interval.

differences (Table 2) tended to be even smaller. Results in terms of relative risk[40] (not shown here) were similar. Help-seeking was associated with insurance coverage but also with greater difficulty in paying for basics. Symptom severity and hypertension also were positively related to help-seeking, as were satisfaction with care and greater myocardial infarction knowledge. Smokers were less likely to seek care for shortness of breath. No other factors were predictive of help-seeking after these variables were controlled. Model fits were satisfactory.

Among those who sought care, Black women had a lower average (log) delay time than White women. Unadjusted effects were −0.86 (95% CI = −1.74, 0.02) and −1.84 (−3.00, −0.67) for chest pain and shortness of breath, respectively. Corresponding unadjusted effects in men were not significantly different from 0 at 0.59 (95% CI = −0.48, 1.65) and −1.14 (95% CI = −2.61, 0.34). Adjusted racial differences (Table 2) were similar in magnitude. Delay time was negatively associated with severity of symptoms and general propensity to seek care. Subjects with elevated cholesterol and current employment had longer delays in seeking care for chest pain. Subjects reporting great difficulty in reaching care had shorter delay times in seeking care for shortness of breath. Model fits were satisfactory.

Care Received by Those Who Sought Medical Attention

Among those who sought care, the relationship between race and care received differed by sex (Table 3). White men tended to have the highest rates of care and White women the lowest, particularly for recommended invasive procedures and cardiac medication, whereas rates for Black men and Black women tended to be similar. An exception was referral to a cardiologist, for which rates were significantly lower for Blacks than for Whites regardless of sex. Controlling for factors other than race did not substantially alter these patterns. The only statistically significant adjusted racial difference occurred for referral to a cardiologist (Table 4), for which the adjusted odds of referral for Blacks were roughly half the corresponding odds for Whites, regardless of sex. For recommended diagnostic procedures (Table 5) and treatments (Table 6), adjusted rates tended to be somewhat higher for Whites among men and lower for Whites among women. Results in terms of relative risk were consistent.

Adjusted differences by sex were more pronounced in Whites than in Blacks, particularly in rates of recommended treadmill tests, recommended invasive procedures, and cardiac medication. Other demographic factors related to care included age, which was positively associated with cardiac medication and diagnosis of a heart problem. Those living alone had a higher rate of hospitalization for myocardial infarction. Symptom severity and risk factors, particularly hypertension, elevated cholesterol, and diabetes, were consistently positively associated with care received, with the exceptions of current smoking and increased body mass

index. Except for current employment, which was negatively related to receipt of care, SES and insurance coverage had little consistent effect on receipt of care after other factors were controlled. Subjects reporting no difficulty in paying for basic necessities had higher rates of recommended invasive procedures. Completion of high school was negatively associated with hospitalization for myocardial infarction, and being uninsured was negatively associated with recommended electrocardiogram. Measures of access, satisfaction, and knowledge also played a small role in predicting care received among help-seekers. Having a usual source of care other than a hospital emergency room was positively associated with recommended treadmill tests but negatively associated with recommended invasive procedures. Adequate time with the doctor or nurse was positively related to being told of a heart problem. Higher levels of myocardial infarction knowledge were linked with higher rates of care. Model fits were satisfactory.

TABLE 3—Rates (%) of Coronary Heart Disease Care Received by Subjects Who Sought Medical Care, by Race and Sex

Type of Care	Black Men (n = 136)	White Men (n = 120)	Black Women (n = 305)	White Women (n = 142)

Discussion

We found that, in an urban low-SES population of Blacks and Whites who were similar with respect to SES and access to care, there were few racial differences in coronary heart disease–related care patterns, either in help-seeking behavior or in care received. Although racial differences varied by sex, rates of help-seeking and care received generally did not differ significantly for Blacks and Whites. Exceptions were delay in seeking care (delays were somewhat shorter for Blacks, particularly for women) and referral to a cardiologist (rates were lower for Blacks). These racial differences persisted after other factors were controlled. The general lack of racial differences in care patterns even before adjustment for other factors may have resulted from the similarity of Black and White subjects with regard to important predictors such as severity of symptoms and employment status.

Although help-seeking behavior was similar for symptomatic men and women, help-seeking women received less care, particularly among Whites. As might be expected, the strongest and most consistent predictors of health care outcomes were risk factors and perceived seriousness of symptoms. The positive relationship between difficulty in paying for basic necessities and help-seeking was consistent with Aday and Andersen's[5] finding that low-income subjects had more hospital admissions and physician visits than those with high incomes, partly because of poorer health. Respondents who were currently employed, and hence likely to be younger or healthier than others, also had longer delays. Shorter delays among those

reporting great difficulty in reaching care may reflect the need to compensate for longer times to reach care. The lack of association between help-seeking and measures of access and satisfaction may have been due in part to respondents' seeking care from sources other than their usual source (e.g., hospital emergency rooms). Negative associations between care received and current employment may reflect the "healthy worker effect"; that is, subjects who received care may have been less likely to be healthy enough to continue working than were subjects who did not receive care. Similarly, those who received care may have been instructed to stop smoking or to lose weight and hence were less likely to continue these behaviors than were those who did not receive care.

Adjustment for socioeconomic factors and insurance coverage had little impact on Black–White differences in care, possibly because racial differences in SES in our sample were somewhat smaller than in the general population: 1980 median census tract annual household income averaged approximately $14 000 for Whites and $11 000 for Blacks in our sample, compared with average annual household income of approximately $19 000 for Whites and $11 000 for Blacks nationally.[41] Although racial differences in SES in this sample were statistically significant, the gap may not have been large enough to yield SES-related racial differences in care patterns, particularly given the similarities of Blacks and Whites with respect to other predictors. In more heterogeneous study populations, SES and insurance coverage may account for more racial differences in coronary heart disease care than we found in our sample. The longer delay times for Blacks than for Whites found by Cooper and colleagues,[4] for example, may have resulted in part from the comparison of poor and working-class Blacks admitted to an inner-city hospital with Whites in more affluent communities. Oberman and Cutter proposed racial differences in education, income, and occupation as possible explanations for lower rates of coronary artery bypass grafting among Blacks.[10] Much of the racial difference in rates of surgery found in the Coronary Artery Surgery Study was due to Whites for whom medical therapy was recommended but who chose surgical treatment,[13] perhaps reflecting Black–White differences in ability to pay for care.

Previous work on help-seeking found lower rates of help-seeking for chest pain[3] and higher rates of delay among nonobstetric and nonpsychiatric hospital admissions[29] in Blacks than in Whites. Neither study, however, adjusted these racial differences for perceived severity of symptoms. Consistent with past research,[9–13] we found lower adjusted rates of recommended invasive procedures in Black men than in White men, although the difference was not statistically significant ($P = .15$). As in recent studies of care patterns by sex,[42,43] the women in our sample, particularly White women, were less likely than men to have recommended invasive procedures even after other relevant factors were controlled. Recommended invasive procedures were positively associated with reporting no difficulty in paying for basics, similar to previous findings that privately insured patients had higher rates of cardiac surgery.[44] In addition, Blacks were significantly less likely than Whites to be referred to a cardiologist, consistent with past findings that Blacks had lower rates of referral to specialists.[45]

Our findings must be interpreted with caution. First, outcome and predictor measures were self-reported and hence

subject to problems inherent in a community-based sample, such as recall bias and misunderstanding of survey questions. Moreover, as Strogatz[3] points out, perception and report of chest pain and other symptoms may differ for Blacks and Whites and thus may not have been adequately addressed by the survey questions regarding symptoms. Any such racial differences in reporting of symptoms could have affected the estimation of racial differences in care patterns. Self-reports of medical conditions, however, including reports of chronic heart conditions,[46–49] have been found to have a fairly high level of agreement with medical records. In addition, the self-reported data collected here did not include clinical measures, which would inform clinical decision making. We note, however, that no judgments were made in this study regarding appropriateness of care received.

Second, it was not feasible to ascertain the timing of outcomes relative to timing of occurrence of symptoms and other predictors. As noted previously,[3] perceptions or reports of symptoms and risk factor status, as well as measures of access, satisfaction, and knowledge, may be results rather than causes of seeking and/or receiving care. When the models for help-seeking and receipt of care were reestimated with measures of access, satisfaction, and knowledge omitted, however, adjusted racial differences changed very little. A related problem is that predictors such as insurance coverage were current measures and hence may not have been relevant to care patterns for symptoms first occurring years earlier. Analyses restricted to subjects with symptom onset less than a year before the interview, however, yielded similar results.

The results presented here raise two main issues needing further examination. First, it is not clear why help-seeking Blacks were significantly less likely than help-seeking Whites to have been referred to a cardiologist, even after risk factors, severity of symptoms, and ability to pay for care were controlled. This result is particularly surprising considering the lack of Black–White differences in reported treatments and procedures normally associated with cardiology practice. When a low significance level (.01) was substituted for a level of .05 to compensate for multiple hypothesis testing,[50] this racial difference remained statistically significant. Second, White women had consistently lower rates of receipt of care than the other three race–sex groups, and women of both races had lower rates of referral to a cardiologist than did men, even after other factors were accounted for. Further study is needed to determine whether these differences can be explained by factors not adequately measured in this study, such as clinical data, or whether they reflect true racial and sex differences in receipt of coronary heart disease–related care. □

Acute Chest Pain in African Americans: Factors in the Delay in Seeking Emergency Care

Kathleen Ell, DSW, L. Julian Haywood, MD, Eugene Sobel, PhD, Maria deGuzman, MD, David Blumfield, MD, and Jia-Ping Ning, BA

ABSTRACT

Objectives. African Americans have been shown to have longer delay times than the majority population in seeking care for acute cardiac problems. The purpose of this study was to determine whether socioeconomic factors affect delay times.

Methods. Structured interviews were administered to 254 African Americans admitted to a public hospital and 194 African Americans admitted to a private hospital for suspected acute myocardial infarction.

Results. Patient characteristics found by multiple regression analysis to affect decision-making and travel time for care-seeking were structural access to care, persistence of symptoms, degree of incapacitation, consultation with a layperson, consultation with medical professionals, and mode of transportation.

Conclusions. Within-group differences were found to be related to socioeconomic status. Strategies to increase knowledge about heart attack symptoms, improve access to care, and improve the socioeconomic status of at-risk African Americans are indicated. (*Am J Public Health.* 1994;84:965–970)

Introduction

According to many studies, African Americans have higher rates of morbidity and mortality from ischemic heart disease than US Whites, both as inpatients and as outpatients.[1–11] Treatment delay blunts the effectiveness of new therapies,[12,13] and African Americans have been shown to receive less specialized care, including coronary artery bypass graft surgery.[14–17] Inordinately long delay times have been documented in this population group,[18] and socioeconomic status (SES) may be an added factor.[19–22] Symptom response is said to be influenced by social and psychological factors including demographic characteristics,[23] previous experience with the medical care system,[24] perceptions of symptom quality and severity,[25] beliefs about care-seeking appropriateness[23] and effectiveness,[24] and accessibility of care. Whether African-American patients who seek prompt care have different characteristics than those who do not is not clear.

We report results from a large study of health care–seeking behavior for acute chest pain. We compare the duration of care-seeking behavior in African Americans of lower and middle SES. We examine associations between demographic and medical care utilization characteristics and the duration of care-seeking behavior among African-American patients who sought care in an emergency room and were subsequently hospitalized for acute chest pain. Duration of care-seeking refers to the length of time between symptom onset and arrival at the hospital. Consistent with the perspective that patients engage in social and psychological processes in deciding to seek emergency medical care,[25] the duration between symptom onset and the decision to seek emergency care (decision phase) is examined separately from the time between decision to seek care and hospital arrival (travel logistics phase).

Methods

Study Sample

Between August 1988 and July 1990, three consecutive case series of African-American, Latino, and non-Latino White patients hospitalized for acute chest pain were recruited from two Los Angeles medical centers: a large urban public hospital where the majority of patients had no insurance and often no other source of medical care, and a large urban private health maintenance organization (HMO) hospital where virtually all patients had insurance and a regular source of care. In this report we examine the African-American sample, which consisted of 254 patients from the public hospital and 194 patients from the private hospital. Because they were recruited consecutively, these patients are presumed to be representative of those receiving care at each medical center. Exclusionary criteria for patients of all three racial/ethnic groups were the following: unwillingness to give consent, severity

of illness, inability to cooperate because of mental status, and alternative clinical diagnoses (i.e., acute pneumonia with pleuritic chest pain, acute costrochondritis). The most common reason for nonparticipation of eligible patients was discharge prior to being interviewed. Participation rates were 58% for African-American patients screened at the public hospital and 65% for those at the private hospital.

Data Collection

All patients were interviewed in the hospital by a bilingual, bicultural interviewer. A detailed structured questionnaire incorporating instruments previously used in surveys of health care behavior and access to care was completed for each study subject. In this report we analyze data from the questionnaire that pertain to the lengths of the decision and travel logistics phases: the former includes time spent in interpreting symptoms, trying self-care methods, and consulting laypersons or medical professionals, and the latter includes time spent in obtaining transportation and actually traveling to the hospital. To record the duration of the care-seeking phases, interviewers verified times by using a benchmark technique whereby the patient was asked to verify the times reported with an event occurrence, daily routine, or break in routine.

Patient characteristics previously shown or hypothesized to influence the duration of care-seeking behavior for acute symptoms were also examined. These included sex, age, marital status, previous history of coronary heart disease, perceived general health status, experience of a prodromal episode prior to the time of acute onset, having regularly seen a doctor within the past year, having had an emergency room visit within the past 6 months, and patients' reported perception and causal attribution of the acute symptoms. These data were obtained with an existing instrument.[25] SES indicators include education and the Hollingshead Two-Factor Index of Social Position.[26] Measures of access to care include health insurance, a regular source of care, and hospital site.

Data Analysis

Bivariate associations were examined with chi-square Wilcoxon and Kruskal-Wallis rank sum statistics and two-way analysis of variance to assess relationships between duration phases and other variables. Multiple regression modeling methods (including both forward inclusion and backward elimination) were used to compare results between study cohorts.[27,28] In view of the wide ranges and skewed distributions of duration measurements, the median test is reported along with mean difference in bivariate analyses; log transformations for the duration variables were used in the multivariate analyses. If care-seeking duration exceeded 1 week, or if the subject reported travel time to the hospital as 0 hours, the subject was deleted from the analyses (n = 9 public hospital and 3 private hospital patients).

Results

The sampling design was expected to yield significantly different patient populations with respect to SES and access to care as well as overall experiences with medical care and previous encounters with health care systems. The data presented in Table 1 show that compared with African-American patients in the private hospital, those in the public hospital were disadvantaged with respect to all measured SES indicators (income, Hollingshead Index, and education), less likely to have health insurance or a regular source of care, and more likely to have had a previous emergency room visit. The public-hospital patients also reported less satisfaction with previous encounters with the health care system. These results support the hypothesis that hospital site is an indicator of access to care.

The total study population mean, median, and range for the time between onset of symptoms and the decision to seek emergency care were 9.14 hours, 1.90 hours, and 0 to 122 hours, respectively; corresponding values for the time to arrive at the hospital following the decision to seek care (i.e., the travel logistics phase) were 5.74 hours, 0.75 hours, and 0.2 to 169 hours. The mean and median durations of the decision and travel logistics phases were compared by SES and access-to-care indicators, sex, previous health status, characteristics of the acute symptoms, and patient behaviors (Table 2). The results demonstrate significant within-group differences among African-American patients. Public hospital patients, those without health insurance, and those who reported usual waits of 1 hour or more to see a physician reported longer times in reaching the decision to seek care. Women experienced a significantly longer travel logistics phase and a longer, but not significantly longer, decision phase than men. Care-seeking durations did not vary between patients having a regular source of care and those not having a regular source of care. The results indicate a trend toward longer times before seeking care among the less educated and lower-SES patients, but these differences were not significant.

Previous history of angina, acute myocardial infarction, or experience of a prodromal symptom phase did not result in significant differences in care-seeking duration; however, care-seeking times were shorter for those with a positive history. In contrast, self-reported health status and being alone at the time of acute symptom onset were associated with a longer decision-phase time. Whether patients attributed their symptoms to a particular cause or did not know the possible cause did not affect the decision-phase duration but appeared to influence the duration of the travel logistics phase. However, when patients perceived their chest pain to be continuous and incapacitating, the duration of care-seeking was significantly shorter than when patients perceived the pain to be intermittent or nonincapacitating (Table 2).

The following specific patient behaviors also influenced care-seeking duration: engaging in self-care by taking medications, informing other members of one's social network about the symptoms, calling a physician or paramedics for consultation, and mode of transportation.

To examine the relative contribution of factors found to distinguish care-seeking duration, multiple regression analyses were conducted. With the variables found to be significant in Table 2 (the variable "waiting time more than 1 hour" was excluded from this analysis because it was not applicable to patients without a regular source of care), the results of analyses using forward inclusion and backward elimination techniques were identical (Table 3). Hospital site, severity of acute symptoms, informing a layperson, consulting a medical professional, and mode of transportation were significant predictors of the duration of the decision phase; having informed a layperson and transportation mode were significant predictors of the duration of the travel logistics phase. Separate analyses for each hospital site (not shown) found that being alone, degree of incapacitation, and transportation were significant predictors of decision-phase duration among public hospital patients ($R^2 = .24$); having told a layperson, symptom pattern, degree of incapacitation, and having taken medication were significant predictors of decision-phase duration among private patients ($R^2 = .18$). Mode of transportation predicted the travel time for each site.

Discussion

This study is the first reported detailed examination of African-American care-seeking behavior for acute chest pain in which comparisons are made between lower- and middle-SES patients and between patients with different levels of structural access to medical care. These results enhance our knowledge about the duration of prehospital behavior, including time spent in deciding to seek medical care and time spent traveling to the hospital, among African Americans who decide to seek emergency care and are subsequently hospitalized. Our findings for African-American patients are similar to other researchers' findings for predominantly White populations,[13,25] but we also uncovered differences specific to the care-seeking behavior of African Americans by access to care, SES, and sex.

The total prehospital median duration found in this study of 2.65 hours (decision phase time = 1.90 hours, travel logistics phase time = 0.75 hours) is longer than the 2.00 hours reported in a study conducted in a predominantly White population.[13] In contrast, an earlier study of African-American patients at Cook County Hospital reported a mean prehospital duration of 20.2 hours, compared with 16.22 for public hospital patients in this study, and a median of 6.4 hours for hospitalized patients with acute myocardial infarction.[18] It is noteworthy that in our study, the mean and median durations of the decision phase were significantly longer for patients receiving care at the public hospital than for those receiving care at the private hospital. We also found that patients without health insurance had a significantly longer decision phase time than those with health insurance. These results are consistent with results from a survey of 12 068 patients hospitalized for various reasons in which it was found that delay in obtaining medical care was 40% to 80% greater for patients who were African-American, poor, uninsured, or without a regular physician.[29]

As found in previous studies,[13,18,25] the time patients spend in reaching the decision to seek emergency medical care accounts for the largest proportion of the total duration of care-seeking behavior. Results from the bivariate analyses shown in Table 2 also indicate a trend in which lower socioeconomic class and limited education further define African Americans who delay the decision to obtain medical care. In addition, our results indicate that African-American women experienced longer prehospital durations following symptom onset than did men. This finding is noteworthy (as well as consistent with results from other studies[18,30]) because women, particularly African-American women, are at greater risk than men for poor coronary heart disease outcomes.[4,5,8,18,29]

The results of the multivariate analyses demonstrate that structural access to care, as indicated by hospital site, was a significant predictor of duration of the decision phase. Our findings provide evidence that socioeconomic factors may influence the care-seeking behavior of African Americans, primarily through a relationship to access to care.

Patients' symptom perceptions and whether they told others in their social network and/or consulted medical professionals were also significant predictors of the duration of the decision phase. These results are consistent with previous research[25,30–32] and indicate that the decision to seek medical care by African Americans is influenced by factors similar to those found to influence the decision in predominantly White populations.[13]

Public education[33–35] about the importance of cardiac symptomatology may have helped influence the care-seeking behavior of patients in our sample. On the

other hand, we found that attributing acute chest pain to a heart attack or other hypothesized cause vs making no causal attribution did not predict the duration of decision making, consistent with previously reported results.[13] Furthermore, our findings raise questions about whether knowledge about cardiac symptomatology is similar among all African Americans. For example, patients receiving care at the public hospital and those without health insurance were more likely to take medication before telling others about their symptoms; this self-care behavior was associated with longer care-seeking durations.

Efforts to locate a family member for advice may forestall prompt action, and consultation with others could result in delaying the decision to obtain emergency care. Previous research found that the delay in obtaining care for acute myocardial infarction was longer when a spouse or others initiated the decision to seek medical care than when the decision was the patient's.[32] On the other hand, a family member could strongly encourage or initiate the decision to seek immediate aid. Similarly, consultation with medical professionals could result in speeding or delaying the decision to seek emergency care.[36] In this study, as in previous research, involving others in the decision-making process prolonged the time African Americans spent in reaching the decision to seek care and lengthened the travel logistics phase. Interestingly, being alone also lengthened care-seeking duration, perhaps because there was no one to act on the behalf of the patient. The wide range in the duration of the travel logistics phase suggests that many patients experience delays in getting to the hospital after deciding to seek care. Perhaps the process of enlisting non–health professionals in travel plans enhances this delay.

[a]Time between symptom onset and decision to seek medical help.
[b]Time between decision to seek medical help and arrival at medical facility.

This study has limited generalizability because it reports the behavior of persons who successfully obtained emergency medical care. Therefore, this study does not enhance our knowledge about persons who decided not to seek care, who sought care elsewhere, or who did not survive long enough to be hospitalized. Additional limitations include sample bias resulting from the exclusion of patients seen in the emergency room but not admitted, or admitted but not interviewed before discharge; measurement error with respect to self-reported data on duration of care-seeking behavior and patients' perceptions, motivations, and behaviors; and the possibility of a chance finding of a significant association owing to the large number of comparisons made.

The results of this study emphasize the value of measuring multiple dimensions of SES,[37] including structural access to medical care, and underscore the value of conducting within-group studies of African Americans.[19] The care-seeking behavior of African Americans in our sample appears to have been influenced by factors similar to those found to influence the behavior of patients from other cultural groups, including symptom progression, degree of incapacitation, and patients' involvement of others in the decision to obtain emergency care and in arranging travel to the hospital. Assurance of access to a source of medical care as a result of HMO membership also appears to influence the time African Americans spend in deciding to seek emergency care for acute chest pain. □

Behavioral Risk Factors: A Comparison of Latinos and Non-Latino Whites in San Francisco

ABSTRACT

Objectives. The purpose of the study was to evaluate differences between Latino and non-Latino White adults in health-related behavioral risk factors.

Methods. Telephone interviews were conducted with 652 Latinos and 584 non-Latino Whites in San Francisco selected by random-digit dialing.

Results. Latino men and women, compared with their non-Latino White counterparts, were less likely to have consumed any alcoholic beverage in the previous month (59% and 29% vs 77% and 75%, respectively), consumed fewer drinks per week (6.6 and 3.0 vs 8.9 and 5.1, respectively), and were more likely to be sedentary (40% and 46% vs 17% and 23%). Latina women were less likely than non-Latina Whites to smoke cigarettes (8% vs 29%), to have ever had a Pap smear (76% vs 93%), and to have ever had a clinical breast examination (81% vs 96%). Multivariate analyses adjusting for sex, age, education, and employment confirmed univariate findings.

Conclusions. Behavioral risk factor profiles by ethnicity help emphasize priorities of health promotion programs for a community. Latino needs include maintenance of limited consumption of alcohol and cigarettes, promotion of regular physical activity, and increasing use of low-cost cervical and breast cancer screening tests. Introduction

Since 1981 the Centers for Disease Control and Prevention (CDC) and collaborating state health departments have been conducting telephone surveys about health behaviors. The surveys have evolved into the Behavioral Risk Factor Surveillance System, which now provides state-specific estimates of health risk behaviors and delivery of clinical preventive services for 45 states and the District of Columbia.[1] These data are used to monitor trends in behavior changes and in planning programs or legislation at the local or state level. Comparisons of health risk behaviors between Whites and African Americans have been reported,[2] and a survey in New York State compared Whites, African Americans, and Latinos on behavioral risk factors for cardiovascular disease.[3] Other studies including large samples of Latinos have not been published.

Regional and national data on selected behavioral risk factors among Latinos, such as cigarette smoking, have been studied.[4–7] In a recent national survey, the overall prevalence of cigarette smoking among US Latinos was 23%, compared with 25.6% for Whites and 26.2% for African Americans; however, this rate reflects a substantially lower smoking rate among Latina women (16.3%) than among Latino men (30.9%).[8] With regard to alcohol use, Latinos have been found to have a pattern of higher abstention rates overall, but Latino men have been found to be more likely than others to use alcohol in excess, especially in binge patterns.[9] In addition, national mortality data show that Latinos are more likely than non-Latino Whites to die from chronic liver disease.[10] Results from the Hispanic Health and Nutrition Examination Survey (HHANES) have shown that, compared with non-Latino Whites, Latina women have a two- to threefold increase in the prevalence of overweight[11] and that Latinos overall have a two- to fourfold increase in the prevalence of diabetes[12] and a similar rate of hypertension.[13] Data from two regional studies indicate that Mexican Americans lead more sedentary lives than non-Latino Whites.[14,15] Finally, the HHANES and other surveys have found that 35% of Mexican Americans, 28% of Cuban Americans, and 22% of Puerto Ricans in the United States do not have any form of health insurance, compared with 10% of Whites and 18% of African Americans.[16] Thus it is not surprising that Latinos report having had fewer medical examinations or recommended cancer screening tests.[17]

To determine local priorities in public health education for Latinos and other ethnic/racial groups, systematic needs assessments are required. We conducted a community survey among Latinos and non-Latino Whites living in the same census tracts of San Francisco to identify differences that may exist in the prevalence of selected behavioral risk factors.

Methods

All subjects were sampled from the 50 census tracts in San Francisco County in which at least 10% of the population was reported to be Latino in the 1980 US census.[18] This sampling universe represented 67% (n = 55 541) of all Latinos (n = 83 373) and 29% (n = 98 250) of all non-Latino Whites (n = 337 118) living in San Francisco in 1980.[18] Telephone prefixes corresponding to the census tracts were identified by means of a reverse telephone directory. A modified Mitofsky-Waksberg[19] method for random-digit dialing was applied to identify eligible respondents.[20]

A household was considered to be eligible if the person answering the telephone identified himself or herself as Latino/Hispanic or non-Latino Caucasian/White, or if that person identified the majority of residents in the household as belonging to one of these groups. Potential respondents were initially asked if they considered themselves or the majority of residents in the household to be Latino/Hispanic. One third of the participating Latino households were randomly chosen to respond to the 24-item behavioral risk factor questionnaire (the remainder responded to a shorter questionnaire on smoking behavior only). Within a given household, the adult between 18 and 65 years of age who had most recently celebrated a birthday was invited to respond to the survey. Potential respondents who refused to participate were not replaced within a household. There were 40 refusals (6%) among Latinos, but refusal rates were not computed for non-Latino Whites. All initial refusals were called a second time and unavailable eligible respondents were called approximately 10 times before they were counted as refusals. Respondents who classified themselves as Latino but who were subsequently found not to be Latino by their responses on family background were excluded from the study.

The questionnaire was administered anonymously by trained, supervised, and experienced bilingual and bicultural Latino interviewers of both sexes after subjects gave verbal consent. Latino participants responded in Spanish (80.8%) or in English (19.2%). The survey instrument and a more detailed description of the interview procedure are available from the authors upon request.

Sex, age, education, employment in the previous 2 weeks, birthplace, and national background (for persons not born in the United States) of respondents were obtained. Latinos also completed a five-item acculturation scale and their scores were dichotomized into less (scores of 1 to <3) and more (scores of 3 to 5) acculturated groups.[21] Smoking behavior items were similar to those of earlier surveys.[7] We selected 24 of the 55 questions (not including questions about demographics) from the 1989 Behavioral Risk Factor Survey (BRFS, provided by CDC) to include items on seat belt use, alcohol consumption, exercise, perceived weight status, and preventive practices. Part of the BRFS questionnaire was found to have acceptable to high item reliability and to be consistent among Whites, African Americans, and Latinos in New York State.[3]

On the basis of responses to the questionnaire, eight behavioral risk factors were identified as outcome (dependent) variables: (1) any use of alcohol in the previous month; (2) binge drinking (defined as having had five or more drinks on one occasion in the previous month); (3) driving a motor vehicle after having had too much to drink in the previous month; (4) current cigarette smoking; (5) infrequent use of seat belts (defined by a response of "sometimes," "seldom," or "never" to a question about how often belts were used); (6) sedentary life-style (defined as no leisure-time physical activity); (7) no routine medical checkup in the previous year; (8) never having had a blood cholesterol test. Additional behavioral risk factors for women were never having had a Pap test, never having had a clinical breast examination, and never having had a mammogram.

Descriptive data were analyzed by standard techniques. Proportions were compared by corrected chi-square tests and continuous variables were compared by analysis of variance. Proportions of behavioral risk factors were age-adjusted to the 1980 US census[18] by the direct method.[22] Ethnic differences (with non-Latino Whites as the referent) on behavioral risk factor rates were evaluated by logistic regression analyses adjusted for sex (women as referent), age (continuous), education (continuous), and employment (being employed as referent). Additional multivariate analyses of the Latino sample were adjusted for acculturation level (more acculturated as referent).

Results

The demographic characteristics of the 652 Latinos and 584 non-Latino Whites interviewed by telephone between June and August 1989 are shown in Table 1. A larger proportion of Latino respondents were women ($P < .01$) and were between 18 and 34 years of age ($P < .001$). Considerably fewer Latinos than non-

Latino Whites had graduated from high school ($P < .001$). Seventy-four percent of the Latino respondents scored as less acculturated, and 77% were born in Latin America. The foreign-born Latinos had been living in the United States for an average of 12.9 years. Thirty percent of the Latinos were of Mexican background, 53% were Central American, and 14% were from other Latin American countries or Spain.

Any Alcohol Use, Binge Drinking, and Drinking and Driving

Table 2 shows the proportions of respondents reporting the selected behavioral risk factors. A significantly lower proportion of Latinos than non-Latino Whites reported any use of alcohol in the previous month ($P < .001$ for both men and women). Latinos consumed significantly fewer drinks per week than their non-Latino White counterparts (6.6 vs 8.9 for men, 3.0 vs 5.1 for women; both Ps $< .001$). Only 6% of Latino men and 0.5% of Latina women reported averaging more than two drinks per day, compared with 16% and 6%, respectively, of their non-Latino counterparts. Although there were no differences in reported binge drinking by ethnicity, a higher proportion of Latino than White men reported drinking and driving at least once. Six percent of Latino men reported having driven a motor vehicle two or more times in the previous month when they may have had too much to drink, compared with 1.3% of non-Latino White men ($P < .01$). Of the 16 Latinos who reported this behavior, 14 were men, 14 were born in Latin America, 13 were 34 years of age or younger, 11 had less than a high school education, and 11 were employed.

Smoking Behavior

The prevalence of smoking among Latina women was very low, although rates for men were similar for both ethnic groups. Latino smokers of both sexes reported smoking fewer than half as many cigarettes per day as non-Latino Whites ($P < .001$ for men, $P = .01$ for women).

Seat Belt Use, Perceived Overweight Status, and Sedentary Life-Style

The proportions of Latinos and non-Latino Whites who reported infrequent use of seat belts were similar (Table 2). However, 5 of the 36 Latinos, compared with none of the 40 non-Latino Whites, who *never* used seat belts reported driving at least twice when they may have had too much to drink.

The proportions of respondents who perceived themselves as overweight were similar for both ethnic groups (for men, 29% of Latinos and 25% of non-Latino Whites; for women, 46% of Latinas and 38% of non-Latina Whites). Latinos of both sexes were significantly less likely than non-Latino Whites to ever exercise and to report exercising daily. In both ethnic groups, similar proportions of self-perceived overweight respondents reported an exercise frequency of at least three times per week.

Medical Examinations and Cancer Screening Tests

After results were stratified by sex, similar proportions of Latinos and non-Latino Whites reported having visited a physician for a routine checkup in the previous year, having ever had a cholesterol blood test (Table 2), and having been told by a physician that they had diabetes or hypertension. Among respondents who were 45 years of age or older, fecal occult blood tests in the previous year were reported less often by Latinos than by their non-Latino counterparts (for men, 34% vs 53%; for women, 49% vs 62%). Latina women reported fewer lifetime Pap smears and clinical breast examinations than non-Latina Whites, and similar proportions of women in each ethnic group reported ever having had a mammogram (Table 2).

TABLE 2—Percentages[a] of Behavioral Risk Factors among Latino and Non-Latino Whites Interviewed, San Francisco, 1989

	Men		Women

No mammogram ever[c]	...	...	26	23	0.88	0.58, 1.34

[a]All proportions are age-adjusted to the 1980 US census by the direct method.
[b]Odds ratio of Latinos reporting the behavioral risk factor compared with non-Latino Whites, adjusted for sex where appropriate, education, age, and employment.
[c]Only for women aged 35 years and older (n = 146 Latinas and 138 Whites).

Multivariate Analyses: Correlates of Behavioral Risk Factors

Multivariate logistic regression analyses showed that Latino ethnicity was a significant predictor for selected behaviors after adjustments were made for sex, education, age, and employment (Table 2). Latinos were more likely to abstain from alcohol (odds ratio [OR] = 3.6, 95% confidence interval [CI] = 2.7, 4.8; $P < .001$) and less likely to have consumed any alcoholic beverage in the previous month (OR = 0.31, 95% CI = 0.23, 0.42; $P < .001$), but none of the other alcohol-related behaviors were significantly associated with ethnicity. Latinos were also less likely to smoke cigarettes (OR = 0.37, 95% CI = 0.26, 0.52; $P < .001$) and more likely to be sedentary (OR = 2.15, 95% CI = 1.59, 2.91; $P < .001$). Finally, Latinas were less likely than non-Latina Whites to report ever having had a Pap smear (OR = 2.41, 95% CI = 1.30, 4.45; $P = .005$) or a clinical breast examination (OR = 3.09, 95% CI = 1.45, 6.59; $P = .003$).

Other demographic variables predicted behaviors independently of ethnicity. Men were more likely to have consumed any alcohol in the previous month (OR = 2.1, 95% CI = 1.7, 2.6), more likely to consume alcohol in a binge

TABLE 3—Percentages[a] of Behavioral Risk Factors among Latino Men and Women Interviewed, by Acculturation Score, San Francisco, 1989

[a]All proportions are age-adjusted to the 1980 US census by the direct method.
[b]Odds ratio of less acculturated (score <3) Latinos reporting the behavioral risk factor compared with more acculturated (score 3–5) Latinos, adjusted for sex where appropriate, education, age, and employment.
[c]Only for women aged 35 years and older (n = 146).

pattern (OR = 3.3, 95% CI = 2.5, 4.5), more likely to drink and drive (OR = 2.7, 95% CI = 1.0, 4.0), less likely to use seat belts frequently (OR = 1.34, 95% CI = 1.02, 1.80), and less likely to be sedentary (OR = 0.75, 95% CI = 0.57, 0.97). Persons with less than a high school education were more likely to abstain from alcohol (OR = 1.4, 95% CI = 1.1, 1.9), more likely to drink and drive (OR = 1.96, 95% CI = 1.3, 2.9), more likely to smoke cigarettes (OR = 1.5, 95% CI = 1.1, 1.9), less likely to use seat belts (OR = 2.2, 95% CI = 1.6, 3.1), and more likely to be sedentary (OR = 2.6, 95% CI = 1.96, 3.50). Persons 35 to 65 years of age were less likely to smoke cigarettes (OR = 0.60, 95% CI = 0.46, 0.76) and more likely to be sedentary (OR = 1.5, 95% CI = 1.1, 1.9); women in this age group were more likely to have had at least one Pap test (OR = 2.6, 95% CI = 1.6, 4.2), more likely to have had at least one breast examination (OR = 1.8, 95% CI = 1.1, 3.0), and more likely to have had at least one mammogram (OR = 7.1, 95% CI = 5.0, 10.0).

Acculturation and Behavioral Risk Factors among Latinos

The effects of acculturation on selected self-reported behaviors among Latinos are shown in Table 3. A lower proportion of less acculturated men ($P = .01$) and women ($P < .001$) reported consuming any alcoholic beverage in the previous month. There were no significant differences by acculturation for either sex in proportions of heavy drinking, binge drinking, drinking and driving, current smoking, or seat belt use. Less acculturated men ($P = .003$) and women ($P < .001$) were more likely to be sedentary. Less acculturated men, but not women, were less likely to have had a routine checkup in the previous year ($P = .009$).

Multivariate analyses showed that less acculturated Latinos were less likely to have consumed alcoholic beverages in the previous month (OR = 0.41, 95% CI = 0.27, 0.62) and to be sedentary (OR = 2.05, 95% CI = 1.35, 3.12). Male sex was the only significant predictor of cigarette smoking among Latinos (OR = 4.2, 95% CI = 3.8, 4.6), although less acculturation was nearly significant (p = .06).

Discussion

To effectively promote healthy behaviors among ethnic and racial groups in the United States, programs need to be based on the specific cultural and behavioral characteristics of each group.[23] This study contrasts the behavioral risk factor profiles of Latinos and non-Latino Whites in San Francisco and provides information on which to base local programs. Compared with a statewide sample in California, this San Francisco sample reported somewhat higher prevalences of binge drinking, drinking and driving, and seat belt nonuse.[24] The proportions that reported smoking cigarettes, having had their cholesterol measured, and having had a mammogram were similar to those in the statewide sample.[24] Only a few substantial differences in behavioral risk factors between ethnic groups were found in our study: these differences were in the consumption of alcohol in the previous month, current smoking, sedentary lifestyle, and having had selected cancer screening tests.

The proportion of abstainers from alcohol was higher and the mean number of alcoholic drinks consumed per week was lower for both Latino men and Latina women. In an analysis of HHANES data, Markides and colleagues found that marriage was the principal demographic factor that consistently predicted less alcohol consumption among Mexican-American men.[25] Although we did not find higher rates of alcohol consumption among Latino men than among non-Latino Whites, our data indicate that a subset of less acculturated Latino men are more likely than non-Latino Whites to combine excessive drinking and driving. However, driving without a seat belt after having had too much to drink was an infrequent high-risk behavior in both ethnic groups, and the proportion reporting this behavior was similar to the 6.3% found among all men in California.[24] In the HHANES, Latinos with more years of education, higher incomes, and higher levels of acculturation reported higher alcohol consumption.[25]

In contrast to the men, 70% of Latina women reported no alcohol use in the previous month, and only 3% averaged one or more drinks per day. Marks and colleagues also found low alcohol use among women from the three major Latino subgroups participating in the HHANES, especially among the less acculturated. This protective effect of traditional Latino culture may be an important element to incorporate into comprehensive health promotion campaigns focused on alcohol use. Markides et al. reported that increasing acculturation was associated with increased alcohol intake among Mexican-American women 20 to 39 years of age.[25] We found that less acculturated Latinos of both sexes were

less likely to consume alcoholic beverages, but the proportion of heavy drinkers was not related to acculturation.

The prevalence of sedentary life-style, defined as no leisure-time physical activity in the previous week, was higher among Latino men and women than among non-Latino Whites. The possible health advantages provided by regular physical activity include a lower likelihood of diabetes.[27] Given that diabetes is two to four times more prevalent among Mexican Americans than among Whites or African Americans,[12] the failure to realize the potential benefits of regular exercise may be of particular importance for Latinos.

Latinos were less likely than non-Latino Whites to report having received a medical examination in the previous year. Differences between ethnic groups were observed for fecal occult blood tests, Pap tests, and clinical breast examinations, but not for mammograms. We did not ask about health insurance status in our survey, and it is likely that these differences reflect the lower coverage rates that have been reported for Latinos.[16] Analyses of the HHANES data have shown that access to health care was the most important predictor of use of preventive health measures for the three Latino subgroups surveyed.[28] Although there is controversy over the roles of regular medical examinations and annual fecal occult blood tests, there is no question about the benefits of screening for cervical[29] and breast[30] cancers. The proportions of Latina women in our sample who had ever had a Pap smear and who had ever had a clinical breast examination were similar to the proportions reported in the HHANES and other surveys and were considerably lower than those found for non-Latina White women.[17,28]

Although the main objective of this study was to identify ethnic differences in behavioral risk factors, the importance of years of formal education was also highlighted by our data. We found more risk behaviors associated with fewer years of educational attainment, including drinking and driving, cigarette smoking, sedentary life-style, and nonuse of seat belts. Thus, we observed differences in risk behaviors by educational attainment and by ethnicity that were independent of each other. The different patterns of risk profiles by years of education within ethnic groups may have implications in the development of health promotion campaigns.[31]

There are several limitations of this study that should be considered in interpreting the results. First, responses to an interview administered over the telephone may not reflect actual behavior, and no validation of self-reports was conducted. A recent study found that comparable estimates were produced by the BRFS and the Stanford Five-City Project Survey (supplemented by physiological data) for selected cardiovascular risk measures, but significant differences were found for measures of body weight.[32] Second, subjects were eligible for this study if they identified themselves as belonging to one of the two ethnic groups and if they lived in a household with a telephone (92% to 96% of San Francisco households have telephones). Variations in self-categorization of ethnicity and in sample selection by random-digit dialing may have affected the results. Third, a comparison of Latino respondents with non-Latino Whites who live in the same census tracts may minimize potential differences in behavioral risk factors influenced by socioeconomic status. Finally, the variables identified as predicting behavioral risk factors need to be interpreted with caution because these results are based on a single cross-sectional survey.

The differences in behavioral risk factor profiles between Latinos and non-Latino Whites emphasize the importance of ethnic group–specific priorities. This is of particular importance in California, where more than 35% of the population is non-White.[33] These data indicate that health promotion programs for San Francisco Latinos should encourage Latinos to maintain low consumption of alcoholic beverages and cigarettes, should educate less acculturated Latino men about the risks of driving a motor vehicle while intoxicated, should promote more physical activity among Latinos of both sexes, and should facilitate the use of low-cost cervical and breast cancer screening tests for Latina women. It is important to conduct health promotion campaigns in Spanish, to use easily understood messages that are culturally appropriate, and to base these messages on research that identifies attitudes and values specific to the target audience. To further define health promotion needs, minority groups in selected states should be oversampled in behavioral risk factor surveys. □

US Public Health Service/HCFA Conference on Primary Care to Be Held in September

The US Public Health Service and the Health Care Financing Administration of the Department of Health and Human Services will convene the Second National Primary Care Conference on September 11 through 13, 1994, at the Fairmont Hotel in Dallas, Tex. The theme of the conference is "Making Primary Care Work Under Health Care Reform." The 2-day conference of panel discussions and plenary and break-out sessions will be attended by primary care and other health care practitioners; national, state, and local policymakers; health care administrators; researchers; educators; and consumers.

Unlike the First National Primary Care Conference that was convened 2 years ago in Washington, DC, and that centered on policy related issues, this conference will address very practical issues and questions. It will provide a national forum that focuses on the primary care changes that are already occurring under state health care reform as they relate to primary care systems, workforce issues, and needs of the underserved. Actual case studies will be discussed with decisionmakers from health care provider organizations, academic health centers, and both the legislative and executive branches of government.

Cosponsors of the conference include the W. K. Kellogg Foundation, the Robert Wood Johnson Foundation, the Josiah Macy Jr. Foundation, the National Academy for State Health Policy, the Henry J. Kaiser Family Foundation, and the Pew Charitable Trusts.

A $250 registration fee covers all conference costs, including materials, meals, reception, and special events. For additional information and to ensure that you receive the program brochure, contact Rose Salton, Social & Scientific Systems, 7101 Wisconsin Ave, Suite 1300, Bethesda, MD 20814; tel (301) 986-4870; fax (301) 913-0351.

Social Influences on the Sexual Behavior of Youth at Risk for HIV Exposure

ABSTRACT

Objectives. Adolescents are increasingly at risk for infection with human immunodeficiency virus (HIV) and other sexually transmitted diseases, especially in poor urban minority communities. To aid the design of interventions in these communities, this study investigated the role of knowledge, attitudes, perceived parental monitoring, and peer behavior in the onset and progression of sexual behavior in children at risk for exposure to HIV.

Methods. A computerized personal interview was administered to 300 African-American 9- to 15-year-old children living in six public housing developments in a large US city.

Results. Although children's knowledge about the hazards of sex increased with age, their sexual activity also increased (from 12% sexually experienced at 9 years of age to more than 80% experienced at 15 years of age). Parental monitoring appeared able to influence sexual activity. However, the perceived behavior of friends was associated with the rate at which sexual activity progressed with age and the degree to which condom use was maintained with age.

Conclusions. The early onset and prevalence of sexual behavior and the importance of peer group influence call for early interventions that simultaneously influence the parents and peers in children's social networks. (*Am J Public Health.* 1994; 84:977–985)

Introduction

Human immunodeficiency virus (HIV) infection is increasingly spread by heterosexual transmission in urban minority communities of the United States and is now the sixth leading cause of death in young people.[1] Large surveys of minority youth suggest that sexual activity is initiated at an early age,[2,3] that protective measures such as condoms are not consistently used, and that use of protective measures may decline with age.[4,5] Minority youths living in poverty are at particularly great risk in view of their high rates of sexually transmitted diseases and adolescent pregnancies.[6]

In the absence of effective medical interventions, educational programs designed to delay the onset of sexual contact and to encourage the use of condoms when contact occurs are needed to protect young people from exposure to HIV as well as other sexually transmitted diseases.[1,7] The present research was undertaken to aid in the design of interventions with high-risk children during the ages when sexual practices are first developing (years 9 through 15).

Most educational interventions to prevent HIV infection focus on the health-related attitudes and behavioral skills of the *individual* as program goals. Although these factors are important in initiating safe behavior, they may not be sufficient to maintain this behavior when social environments continue to encourage risk.[8,9] Social environments are especially critical during the early adolescent years when standards for behavior are often set by parents and peers.[10] Even if individual attitudes and skills support safe behavior, social norms can influence the onset and progression of risky behavior.[5,11,12] Although research suggests that sexual expression, especially in boys, is greatly influenced by hormonal changes that occur naturally during maturation,[13,14] perceived peer behavior may still define boundaries for the expression of hormonal influence.[15]

Parents and adults also play a major role in socialization and control a good deal of children's activities. Parenting styles are related to several aspects of childhood development,[16,17] including risky sexual behavior[18] and delinquency.[19] Parental supervision and monitoring may be particularly relevant to sexual expression by communicating parents' concern about risky behavior and raising children's awareness of the costs of such behavior.

It is critical to understand the social processes that influence sexual expression so that prevention programs can be designed to incorporate these influences.[20] The present research was designed to provide an understanding of the social influences of parents and peers on the initiation and adoption of sexual practices in a population at great risk for exposure to sexually transmitted diseases and HIV.

This paper was accepted September 1, 1993.

Methods

A survey of children 9 to 15 years of age was conducted from March to May 1992 in six public housing sites in a large US city. The survey was conducted in a residential setting (rather than in schools or clinics) to increase the chances of reaching high-risk children. Public housing was selected because it ensured that residents would be close to or below official poverty levels. The present sites contained approximately 4000 households with approximately 1600 children between the ages of 9 and 15 years. Virtually all of the households were African American, more than 80% were headed by women, and all received some form of publicly financed assistance.

Prior to conducting the survey, project staff met with public housing officials and resident councils to secure their endorsement of the survey and cooperation in recruiting respondents. Children were recruited with the assistance of several adult residents and with the use of posters and letters to residents urging them to bring their children to an interview location (a public room at the site) during scheduled hours. Interviewing was conducted for about 2 weeks per site. There was a tendency to recruit more children of younger ages under the assumption that their sexual activity would be less developed and would require larger numbers to achieve stable estimates. Informed consent was obtained from both caretakers and children, and each child received $5 for participating. In order to assess the test–retest reliability of the interview, a subsample of 34 children was recruited to return about a week later to repeat the interview. The distribution of these children in age and gender was similar to that of the total sample.

The interview was conducted with a Macintosh computer that was programmed to administer the questions orally over earphones. The program provided a personalized version of the interview to take into account the child's gender, age, and level of sexual development. An adult interviewer explained the use of the computer and remained available to answer questions, but children completed the interview largely on their own. The major purpose for using a computerized interview was to permit children to respond with as much confidentiality as possible while still maintaining a high level of attention. A written questionnaire would have posed comprehension problems for younger children and those with weak reading skills. With the computerized interview, children listened to the questions privately over earphones, and only the computer could "hear" their responses (which were entered by using a mouse to press buttons visually displayed on the screen). Most of the responses were of the yes/no variety and, in all cases, were explained during the interview. The interview was self-paced; children could repeat any question that was not clear on the first presentation, and they could skip any question that they could not or did not want to answer. The entire interview took about 45 minutes.

The interview was divided into several sections, the results of three of which are reported here. The opening section focused on the child's typical activities and included an in-depth discussion of his or her friends. Children were asked to name up to nine same- and opposite-sex friends and to report on various characteristics of each friend.

The second section of the interview focused on the child's sexual behavior. Initial questions asked about kissing and then asked whether the child had ever had sex with anyone. Earlier focus groups with children across our age range indicated that they knew the meaning of this question.[21] For those children more than 10 years of age who reported having had sex, the interview went on to ask whether they had engaged in sex in the last 3 months. In addition, children were asked whether they had ever used birth control in general and condoms in particular and whether they had used a condom on the last sexual contact. Children who were 9 and 10 years of age were asked only whether they had used a condom on the last occasion. Children who reported not yet having had sex were asked whether they thought they would have sex in the next year.

On the basis of these responses, two scales of sexual practice were constructed. One was a scale of sexual activity ranging from never having had sex (0) to having had sex in the last 3 months (1.5). The scale ranged from only 0 to 1 for 9- and 10-year-old children because they were not asked about sex in the previous 3 months. We assumed that, for children of this age, any sex would be rare enough that further differentiation would be uninformative. The scale had a test–retest reliability of .86, suggesting that it was a stable indicator of sexual activity.

A second scale was constructed to assess the level of condom use (among those children who had ever engaged in sex). The scale ranged from never having used a condom (0) to having used a condom on the last sexual occasion (2). The scale had only 2 points for children 9 and 10 years of age (0 or 2); older children who reported use of condoms were further divided into those who did (2) and those who did not (1) use one on the last occasion. This scale also had a high test–retest reliability (r = .83).

To assess the influence of peers, two questions asked about the behavior of the friends who had been listed in the beginning of the interview. One question concerned the respondent's perception of how many of his or her friends "have had sex" (none, some, or most). The other question asked how many of the respondent's friends (of those whose friends had ever engaged in sex) used condoms (none, some, or most). These items also had adequate test–retest reliabilities (r's = .67 and .57, respectively).

To assess the influence of caretakers, a series of six questions addressed the frequency with which the child's parents or other responsible adults monitored the child's social behavior outside the home (never, sometimes, or always). Two questions asked whether caretakers generally knew where the child was and whether they expected a call if the child was late. The other four questions asked whether caretakers knew whom the child was with and details of the child's activities. The two sets of items were combined into separate indices of caretaker monitoring that were only moderately correlated (r = .41). The shorter, "whereabouts" scale had an internal consistency score (Cronbach's alpha) of .51, and the longer, "detailed knowledge" scale had a Cronbach's alpha of .70. These scores suggested that the scales measured consistent aspects of caretaker behavior. The more internally consistent scale was also more stable over time (r = .44 vs .33).

All children were also asked to rate, on a 5-point scale ranging from "very bad" to "very good," how they would feel if they were to have sex in the next year (test–retest r = .74). This scale was designed to measure the child's attitude toward having sex and was included as a diagnostic score to interpret the relations between social influences and sexual behavior. The final section of the interview contained a series of knowledge questions about HIV and acquired immunodeficiency syndrome (AIDS) that were adapted from tests frequently used in evaluating AIDS education.[22,23] These

brief statements were answered as true or false. Four items stated common misconceptions about the transmission and cure of HIV infection. Two items assessed the importance of using condoms to prevent transmission. Three other items referred to hazards of sex in transmitting HIV. Our interest was in assessing deficits in knowledge about HIV and in determining whether those deficits were related to sexual practices or to peer and caretaker influences. At the close of the interview, project staff gave children explanations of the correct answers to all of the questions and gave them an opportunity to ask additional questions about AIDS.

Results

Of the 316 children who were screened to participate in the survey, 300 successfully completed the interview (160 girls and 140 boys), approximately 50 respondents per housing site. Table 1 contains the numbers of children by age and gender, as well as the results for the sexual activity questions. As many as 12% of the 9-year-old children reported having had sex. By 15 years of age, all of the boys and more than 80% of the girls claimed to have had sex. Of those children who had engaged in sex, high proportions also claimed to have had sex in the last 3 months. A multiple logistic regression analysis of ever having had sex revealed that both age, $\chi^2(1) = 5.9$, $P < .05$, and gender, $\chi^2(1) = 31.8$, $P < .05$, predicted sexual activity. There was no interaction between gender and age, $\chi^2(1) = 0.08$, $P = .78$.

Figure 1 shows the sexual activity scale scores for boys and girls as a function of age. The results of a multiple regression analysis (Table 2) indicated that sexual activity increased at the same rate with age in boys as in girls but that boys had a consistently higher level of sexual activity at any age.

Table 1 also contains the percentage of children at each age and for each gender who reported ever having used a condom and having used a condom on the last occasion of sex (among sexually experienced respondents). Experience with condoms was quite high. Of the children over 10 years of age, more than 90% of the girls and more than 75% of the boys had used a condom. Rates of use for the last sexual occasion were also high. Because the number of respondents within each age group was small, we aggregated

[d]Total based on ages 11–15 years (n = 95).
[e]Total based on ages 11–15 years (n = 66).

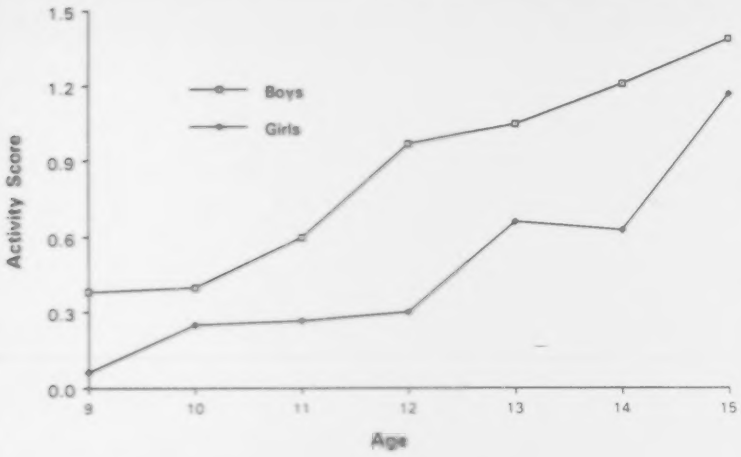

FIGURE 1—Mean sexual activity scores, by age and gender.

the results by age into two categories, 9 to 12 years of age and 13 to 15 years of age. A regression analysis of the condom use score (Table 3) revealed no significant differences by age or gender, although the tendency for girls to report more use of condoms was marginally significant ($P < .10$).

Table 4 contains the intercorrelation matrix for sexual activity and condom use with age, gender, and the other major variables. Because both age and gender were correlated with the other variables, we conducted multiple regression analyses to identify the unique relations of the other variables with sexual activity and condom use.

Parental Monitoring

Table 5 contains the results for the two parental monitoring scales. As seen in Table 4, girls perceived more of both types of parental monitoring, but only detailed knowledge was related to differences in age. Older children perceived that caretakers monitored the details of their social behavior less than younger children. To assess the relation between parental monitoring and sexual activity, we added the detailed knowledge scale as a predictor of sexual activity (Table 2). This analysis confirmed that greater monitoring was associated with less sexual activity holding constant the gender and age of children. There was no evidence of an interaction between age and parental monitoring, and monitoring was not associated with condom use (Tables 3 and 4).

Peer Behavior

Table 6 contains the results for perceived sexual experience and condom use of peers. As seen in Table 4, both scores were positively related to age, but the perceptions of boys did not differ from those of girls. Peer perceptions were also unrelated to parental monitoring. When perceived sexual experience of peers was used to predict sexual activity (Table 2), the interaction between age and perceived peer behavior was a significant predictor. As seen in Figure 2, the more that children perceived their peers as having engaged in sex, the greater their expression of sexual activity with age.

The regression analysis of condom use among sexually experienced children (Table 3) indicated that this protective behavior also varied as a function of the interaction between age and perceived peer behavior. As seen in Figure 3, children who perceived that most of their friends were using condoms were the only group to maintain condom use across age. Among children who perceived lower rates of condom use among friends, younger children tended to report more condom use than older children.

Attitude and AIDS Knowledge

To understand the influence of caretakers and peers, we explored the potential mediating roles of attitude toward sex and AIDS knowledge. Table 7 contains the results for the attitude toward sex and knowledge items. As seen in Table 4, attitude toward sex was directly related to age and was more favorable for boys than girls. As would be expected, attitude was also strongly related to sexual activity. To determine whether attitude could explain the associations of parental monitoring or peer perceptions with sexual activity, attitude was added to the multiple regression equations prior to the social variables. This analysis indicated that, with attitude in the equation, the impact of parental monitoring declined from $B = -.11$ ($P < .05$) to $B = -.09$ ($P < .10$). However, neither the simple relation with perceived peer behavior nor the interaction with age changed as a result of holding constant attitudes toward sex.

As a group, children tended to score above chance levels on each type of knowledge question (general misconceptions, condom protection, and sexual risks). This was especially true for questions about the risks of sexual transmission. However, children 9 years of age did not respond at a better than chance rate to the misconception and condom questions. Correct responses to these questions tended to increase with age and to increase more for girls than boys. None of the knowledge measures was related to sexual activity once age and gender were controlled; thus, these variables could not be used to explain the effects of parental monitoring or peer behavior. Condom use was also not associated with any of the knowledge measures, nor was it predicted by attitudes toward sex. We did not measure attitudes toward condoms per se.

Discussion

The rates of sexual activity we observed confirm our assumption that minority youths living in poverty represent a particularly high-risk population for exposure to HIV and other sexually transmitted diseases. Although our sample was young relative to national US samples, the present rate of sexual activity among 14- and 15-year-old boys was comparable to the rates reported for 18- and 19-year-old African-American boys in a representative survey conducted in 1988.[3] The present rate for girls at 15 years of age was comparable to the rates for girls 18 to 19 years of age in a different representative survey of African-American girls conducted in 1988.[2]

The present results also validate the hypothesis that differences in the onset and progression of sexual activity are related to social influences. The older the children in this sample, the more knowl-

edgeable they were about the hazards of sex and the benefits of condoms. In spite of this knowledge, their sexual activity increased as a function of age, especially when the perceived sexual behavior of peers was supportive. Importantly, they were more likely to engage in sex when they perceived low levels of monitoring by their caretakers and more likely to use condoms if they believed that their peers used them.

Although peer perceptions were more strongly related to sexual behavior than parental monitoring, it is not possible to draw conclusions about the relative magnitude of each influence. Because the test–retest reliabilities of parental monitoring scores were lower than those of peer perceptions, the resulting associations with sexual behavior may also have been lower. Nevertheless, the results do suggest that the two types of influence operated through different mechanisms. Monitoring was sensitive to both age and gender, as was attitude toward sex. Peer perception, however, was largely unrelated to monitoring, was sensitive only to age, and remained related to sexual activity once attitude and monitoring were held constant. This pattern suggests that monitoring was part of a process that influenced sexual attitudes and behavior separately from peer influence. It is not likely that greater monitoring reduced children's opportunities to engage in sex because this should have depressed the rate of change of sexual activity with age. However, there was no evidence of this effect.

The results for perceived peer behavior suggest that peers influenced normative boundaries for acceptable behavior rather than individual attitudes. If the motivation to engage in sex increases with age (as it appeared to do), then this increase should be expressed to a greater degree when peer norms are more favorable for sex. This would result in the observed greater rate of sexual activity with age for children with favorable group norms. It is also plausible that greater peer pressure for condom use would make nonuse of condoms less acceptable. If the individual motivation to use condoms declines as adolescents age (as considerable survey evidence suggests), then this decline should be more pronounced when peer norms are less favorable for condom use, precisely the result that we found.

The finding that condom use tended to decline with age except among children who perceived that most of their friends also used condoms suggests the powerful role that peer behavior can have on this important risk-reducing behavior. However, it is not clear why some children use condoms less as they mature. This repeated finding in surveys of adolescents requires further research.[5] One possibility is that, as children age, they find partners whom they regard as stable and feel less need for condoms. Another is that condom use interferes with sexual enjoyment and is difficult to maintain regardless of the partner. Finally, it is possible that

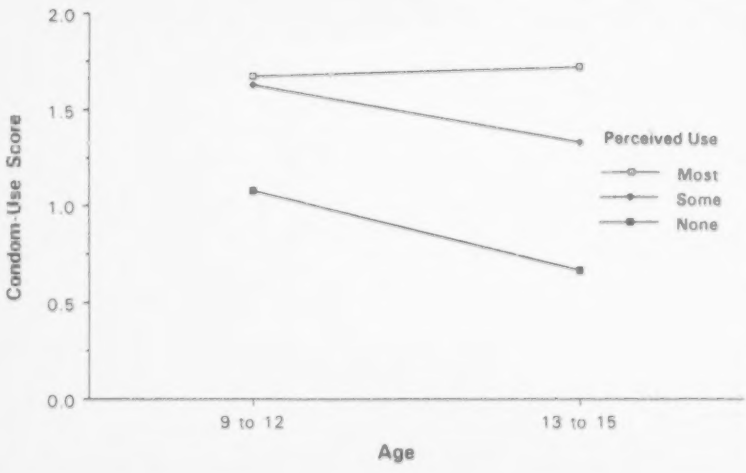

FIGURE 3—Mean condom use scores, by age and proportion of friends perceived to use condoms (none, some, most).

recent educational campaigns have succeeded in reaching younger children who are just becoming sexually active to a greater degree than older children. If this is true, our results could reflect a cohort effect rather than a stable trend that adolescents undergo as they become more sexually experienced.

Alternative Explanations

Previous research with adolescents[13,14] suggests that the development of sexual behavior in boys is largely dependent on hormonal levels and that these influences can explain sexual behavior better than social processes. However, consistent with more recent research,[15,24] the present results suggest that parental and peer behavior also exert influence on the sexual expression of boys and girls. To argue otherwise would require, in the case of monitoring, that parents monitor children less to the degree that children are sexually active, a possible although implausible explanation.

In the case of peer influence, a hormonal–maturational explanation might assume that children's perceptions of peers are simply a consequence of their own sexual behavior.[24] That is, children choose friends (or claim to associate with others) who are similar to themselves in interests and social characteristics, including sexual behavior. However, the data were inconsistent with this interpretation. If peer perception merely reflects individual behavior, the relation between age and sexual behavior should not depend on peer perceptions.

Another explanation consistent with similarity-choice mechanisms is that children's sexual practices become more important for friendship choices as children age, resulting in greater alignment between behavior and peer perception. If this interpretation were valid, however, it would only reinforce the importance of peer influences as a source of social support for risky sexual behavior and increase the need to consider social networks as a point of intervention.

Implications for Intervention

In this research, we have demonstrated that minority preadolescents and early adolescents living in poverty are at great risk for acquisition of HIV and other sexually transmitted infections. Through the use of sensitive interview techniques, we have demonstrated that these children's rates of reported sexual activity are comparable to those among young people 3 and 4 years older (according to nationally representative samples). These results indicate the need for interventions that target children in high-risk environments at earlier ages than national surveys would indicate.

This analysis also has several implications for intervention design. Consistent with the conclusions of many prevention researchers,[5] we found that knowledge about the hazards of unprotected sex is not sufficient to overcome the host of other influences that increase risky sexual behavior. Furthermore, our results suggest that even changing individual attitudes and skills may not undo the influence of peer norms. Even if parents could monitor their children more carefully, the rate at which their children's sexual activity progresses appears to be influenced by peers. Moreover, interventions designed to affect attitudes or abilities regarding condoms may have limited impact if peers do not support condom use. Nevertheless, our results suggest two strategies for reducing the prevalence of

risky sexual behavior in this age group. One strategy would be to encourage parents of children's friends to join together to monitor the behavior of their children. If parental monitoring were shared across friendship networks, peer influences might also transmit the influences of parental monitoring. Although shared caregiving is a traditional practice among African-American families,[25,26] parents' efforts may benefit from interventions designed to increase the shared monitoring of their children. Another strategy would be to promote the appeal of delayed sexual activity (or of continued use of condoms) to children within their friendship networks so that the social norms of peers would favor risk reduction rather than enhancement. □

The Adequacy of Prenatal Care and Incidence of Low Birthweight among the Poor in Washington State and British Columbia

Steven J. Katz, MD, MPH, Robert W. Armstrong, MD, PhD, and James P. LoGerfo, MD, MPH

ABSTRACT

Objectives. The purpose of this study was to examine differences in adequacy of prenatal care and incidence of low birthweight between low-income women with Medicaid in Washington State and low-income women with Canadian provincial health insurance in British Columbia.

Methods. A population-based cross-sectional study was done by using linked birth certificates and claims data.

Results. Overall, the adjusted odds ratio for inadequate prenatal care in Washington (comparing women with Medicaid with those with private insurance) was 3.2. However, the risk varied by time of Medicaid enrollment relative to pregnancy (2.0, 1.0, 2.7, 6.3; for women who enrolled prior to pregnancy, during the first trimester, during the second trimester, or during the third trimester, respectively). In British Columbia, the adjusted odds ratio for inadequate care (comparing women receiving a health premium subsidy with those receiving no subsidy) was 1.5 for women receiving a 100% subsidy and 1.2 for women receiving a 95% subsidy. The risk for low birthweight followed a similar trend in both regions, but there was no association with enrollment period in Washington.

Conclusions. Overall, the risk for inadequate prenatal care among poor women was much greater in Washington than in British Columbia. Most of the difference was due to Washington women's delayed enrollment in Medicaid. In both regions, the poor were at similar risk for low birthweight relative to their more affluent counterparts. (*Am J Public Health.* 1994;84:986–991)

Introduction

New federal and state health policy initiatives may result in the gradual dissolution of Medicaid. In its place, federal and state governments may provide subsidies to the poor to sponsor insurance coverage under one of many regional health insurance purchasing groups. Thus, health insurance coverage for the poor may be merged with coverage for more affluent persons. These changes, already under way in some states such as Washington State, will have an important potential impact on health care for the poor.

A primary motivation for these reforms is the checkered performance of the Medicaid program. For instance, though Medicaid has been credited for narrowing the gap in infant morbidity and mortality between the poor and the more affluent, progress has stagnated.[1–3] Recent expansions of the program have shown little or no improvement in the utilization of prenatal care or outcomes among new Medicaid enrollees.[4–6]

Reasons for these failures fall into two broad categories.[7] First, despite Medicaid reforms, insurance-related barriers persist. Providers resist caring for patients whose insurance payments for prenatal care and delivery are much lower than prevailing community fees.[8,9] Because Medicaid eligibility may include the precondition of pregnancy, some women must first become pregnant before qualifying for coverage, which may result in late initiation of prenatal care.[10,11] Second, optimal insurance coverage alone does not address problems associated with poverty that may contribute to inadequate prenatal care and poor outcomes among the poor such as limited education, being unmarried, teenage pregnancy, and lack of transportation.[5,12] Although it is hoped that eliminating Medicaid will narrow the gap between the poor and more affluent, the results remain uncertain.

The Canadian health insurance program is an important benchmark for how proposed US reforms might affect health care for the poor because the program is uniform and universal. Thus, structural and economic barriers to care are minimized. Payments to physicians are uniform, which eliminates the effect of low payment on provider participation. Finally, the poor are not identified and potentially stigmatized by the insurance plans.

We compared differences in the adequacy of prenatal care and the incidence of low birthweight between poor and more affluent women in Washington State and British Columbia delivering during a period from 1987 through 1989. We chose these two regions because they are similar in demographic characteristics and in the organization of obstetrical care. We hypothesized that the elimination of barriers related to health insurance in Canada narrows the kind of gaps in adequacy of prenatal care and incidence of low birthweight between poor and

more affluent women observed in the United States.

Methods

Study Population

The population was all singlet births in nonfederal hospitals in Washington State from July 1, 1988, through December 31, 1989 (n = 95 401) and in British Columbia from January 1, 1987, through December 31, 1988 (n = 79 638).

Data Source

In Washington, information from birth certificates, hospital discharge abstracts, and the Medicaid enrollment file was linked and combined for 96% of births (n = 95 401).[13] In British Columbia, information from birth certificates, physician claims, and hospital discharge abstracts was linked and combined for 92% of births occurring during the study period (n = 72 831). The distribution of demographic factors and health services utilization among women with linked records compared with women excluded because of unlinked records was similar in the two regions. Details of the record linkage process are available elsewhere.*

Definitions of Variables

Adequacy of prenatal care. The principal dependent variable was the modified Kessner index, a quantitative measure of the adequacy of care that considers the timing of the first prenatal visit (the month prenatal care began) and the total number of prenatal visits adjusted for gestational age.[14] A woman is categorized as receiving inadequate prenatal care if the first visit occurred during the third trimester of pregnancy or if the total number of visits was very low (regardless of the timing of care).

In Washington State, the variables for the number of prenatal visits, the month of pregnancy in which prenatal care began, and gestational age were obtained from the birth certificate. Gestational age was calculated from the date of the last menstrual period and the date of delivery. When only the day of the last menstrual period was missing (20% of cases), we imputed the missing day at 15. An additional variable, the clinical impression of gestational age, was used if the last-menses date was missing entirely. Eighty-six percent of records were complete for all variables in the analysis with the Kessner index.

Information about the month that prenatal care began may be more accurate than information on the number of visits.[15] The Washington State Department of Health validated these data from birth certificates by using medical records in 1987. Fifteen birth certificates from all delivery hospitals (n = 765) were selected. When present on the certificates, information regarding menses date, the month prenatal care began, and number of prenatal visits differed from medical records in 9.5%, 4.3%, and 9.7% of cases, respectively.[16] To minimize measurement error we eliminated prenatal visit utilization from the measure of adequacy of prenatal care by using only the month prenatal care began as the dependent variable. Inadequate care was defined as the initiation of care during the third trimester. Ninety-five percent of cases were complete for all variables when this variable was used in the analysis.

In British Columbia, information about use of prenatal services is not contained on birth certificates. Instead, we used claims data to calculate the timing of the first prenatal visit and the total number of prenatal visits. We obtained insurance enrollment dates to exclude women who did not continuously reside in the province during the study period. The month of pregnancy in which prenatal care began was calculated from the first prenatal visit date, the date of delivery, and the gestational age (obtained from birth certificates). Ninety-eight percent of records were complete for all variables.

Insurance status. In Washington State we used the Medicaid enrollment file to identify women whose delivery was insured under Medicaid. During the study period, any woman was eligible for Medicaid if the family income was 60% or less of the poverty level (approximately $7500 for a family of three). However, any pregnant woman could qualify if the family income was 100% or less of the poverty level (approximately $12 600 for a family of three). Self-pay and private insurance status was identified from the hospital payer code.

In British Columbia, all residents were required to pay a health insurance premium that was subsidized for low-income women. A resident received a 100% subsidy if he or she qualified for provincial income assistance or received a 95% subsidy if he or she had a taxable income that was low but not low enough to qualify for provincial income assistance. A family of three was eligible for the premium waiver if the annual gross income was under US$9600 or a 95% subsidy if the annual gross income was greater than US$9600 but less than US$16 000.

Demographic variables and birthweight. Birthweight, maternal age, marital status, and gravidity were obtained from birth certificates. Information on maternal race, obtained from birth certificates, was available only for Washington.

Analysis

We examined the adequacy of prenatal care and the incidence of low birthweight separately for each region using logistic regression. The first part of the analysis modeled the probability of inadequate prenatal care as a function of insurance status in Washington or subsidy status in British Columbia. The dependent variable was set equal to 1 if prenatal care was inadequate (Kessner score equal to 3) or 0 if prenatal care was adequate or intermediate (Kessner score equal to 1 or 2). A second dependent variable was modeled and set to 1 if the first prenatal visit occurred during the third trimester or 0 if the first prenatal visit occurred before the third trimester.

In the second part of the analysis we modeled the probability of low birthweight (less than 2500 g) as a function of insurance or subsidy status for each region separately. In Washington, the principal independent variable was insurance status: Medicaid (enrolled before pregnancy, during the first trimester, during the second trimester, or after the second trimester), private insurance, or self-pay. The reference category was private insurance. In British Columbia, the principal independent variable was subsidy status (complete waiver or 95% premium subsidy). The reference category was women who did not receive a subsidy.

In both parts of the analysis, we controlled for maternal age, number of

Gravidity, mean no.	1.3	1.6	1.3

previous pregnancies, marital status, and race. We controlled for race by restricting a secondary analysis in Washington to non-Black and non-Hispanic women. This resulted in a racial composition in Washington that was comparable to that in British Columbia (predominantly Caucasian with similar proportions of Asian and Aboriginal minorities). The final logistic regression models contained covariates describing insurance status in Washington or subsidy status in British Columbia, maternal age, maternal age squared, dichotomous variables indicating the total number of previous pregnancies (0 to 8 or more), and a dichotomous variable indicating marital status. Second-order interaction terms were tested, but they were not included because they did not change the regression coefficients for insurance or subsidy status in the main models.

Results

Table 1 shows the distribution of maternal age, gravidity, marital status, and race by insurance status in Washington State. Demographic characteristics of women with Medicaid are broken down by period of enrollment. Overall, women with Medicaid were much more likely to be younger than 20 years, single, and non-White than were women with private insurance. Most women with Medicaid who enrolled before pregnancy qualified on the basis of Aid to Families with Dependent Children. These women were significantly poorer (based on eligibility requirements), older, more likely to be single, and more likely to have children than women enrolled during pregnancy. Importantly, 50% of Black women with Medicaid enrolled before pregnancy, whereas 70% of Hispanic women with Medicaid enrolled after the first trimester of pregnancy.

Table 2 shows the distribution of age, marital status, and gravidity by subsidy status in British Columbia. Women receiving no health premium subsidy were similar to women receiving private insurance in Washington. Women receiving a 100% subsidy were similar to women receiving Medicaid in Washington. The demographic factors of women receiving a 95% subsidy were intermediate between women receiving no subsidy and women receiving a 100% subsidy.

There was a wide distribution of Medicaid and subsidy deliveries across hospitals in both regions. In 75% of the 68 Washington hospitals delivering more than 100 women per year, the proportion of Medicaid births was 20% or more. In 75% of the 65 British Columbia hospitals with 100 or more deliveries per year, the proportion of subsidy births was 15% or greater. Similarly, there was a wide distribution of low-birthweight infants across hospitals in both regions.

Table 3 shows the number of observations and the proportion of women with inadequate prenatal care among women receiving Medicaid compared with women receiving private insurance in Washington and among women receiving a premium subsidy compared with women receiving no subsidy in British Columbia. Also shown are odds ratios and 95% confidence intervals with and without adjustment for covariates. The large differences between unadjusted and adjusted odds ratios reflect the distribution of age, marital status, and gravidity by payer status and the strong effect of these covariates on utilization. Women who enrolled before pregnancy (women receiving Aid to Families with Dependent Children) were at higher risk for inadequate prenatal care than were women receiving private insurance. Women who enrolled during the second trimester were at much higher risk and women who enrolled after the second trimester were at the highest risk.

Low-income women in British Columbia were also at risk for inadequate prenatal care and low-birthweight infants. The adjusted odds ratio for inadequate

prenatal care was somewhat lower for women receiving a 100% premium subsidy waiver than it was for women insured with Medicaid before pregnancy in Washington. Women receiving a 95% health premium subsidy had a lower risk of inadequate prenatal care than did women receiving a 100% subsidy. Importantly, these results were the same when the month prenatal care began was used as the dependent variable for inadequate prenatal care instead of the Kessner index.

Overall, women with Medicaid were at higher risk of having a low-birthweight infant than were women with private insurance in Washington (Table 4). The risk of having a low-birthweight infant was similarly high among women receiving a 100% subsidy compared with women receiving no subsidy in British Columbia. However, despite the strong association between enrollment and adequacy of prenatal care in Washington, there was no association between enrollment and the incidence of low birthweight. We repeated the analysis of inadequate prenatal care and low birthweight in Washington excluding Hispanic and Black women. Excluding these women had a negligible effect on the adjusted odds ratio for inadequate prenatal care among Medicaid recipients. However, it did result in a slight increase in the adjusted odds ratio for low birthweight among Medicaid recipients who enrolled during the third trimester (from 1.3 to 1.5). These results are likely explained by the risk of inadequate prenatal care and low birthweight among Hispanic women (predominantly of Mexican or Central American descent). Table 1 shows that these women represented only 4% of births, but they represented 13% of women with Medicaid and 23% of women with Medicaid who enrolled during the third trimester. However, Hispanic women who enrolled late in pregnancy were not at risk for low birthweight. These findings are consistent with results from other studies.[1,3,17] By contrast, Black women who enrolled late were at increased risk of having low-birthweight infants. However, Black women represented only 7% of women receiving Medicaid and only 4% of women with Medicaid who enrolled during the third trimester. Thus, overall, controlling for race by restriction had a minimal impact on the results.

TABLE 3—Odds Ratios for the Risk of Inadequate Prenatal Care for Women with Medicaid vs Private Insurance Coverage in Washington and for Premium Subsidy vs No Subsidy in British Columbia

Discussion

We found that, compared with their more affluent counterparts, women receiving Medicaid in Washington State were much more likely to have inadequate prenatal care than were poor women in British Columbia (adjusted odds ratio of 3.2 in Washington compared with 1.5 in British Columbia). However, most of the difference between Washington and British Columbia was due to delayed enrollment in Medicaid. Women who enrolled in Medicaid before pregnancy were only slightly more likely to have inadequate care than were women in British Columbia (odds ratio of 2.0 in Washington vs 1.5 in British Columbia).

Although the period of Medicaid enrollment was strongly associated with the adequacy of prenatal care, it was not associated with the incidence of low birthweight. These results are consistent with other studies that have found little relationship between the utilization of prenatal care (as expressed by the timing and number of visits) and low birthweight.[1] Though many organizations have endorsed the importance of regular prenatal care visits in reducing the incidence of low birthweight, the relationship, overall, appears modest. The occurrence of low

birthweight is influenced by many complex biological and social factors that may not be greatly affected by prenatal care. Women who may particularly benefit from improved prenatal care because of being at high risk for adverse outcomes represent a small proportion of all women giving birth. Furthermore, utilization measures alone do not address the content of prenatal care visits, an important factor in the quality of care.[18] These factors limit the power of observational studies to detect associations between the utilization of prenatal care and birth outcomes. In Washington, this relationship may be further obscured by the racial composition of the study population. Hispanic women, who were not at increased risk for low-birthweight infants, constituted 23.4% of third-trimester enrollees in Washington Medicaid, but only 3.1% of those with private insurance.

Women who were enrolled in Medicaid before pregnancy represented a unique group among all Medicaid enrollees. These women, who qualified under federal (Aid to Families with Dependent Children) or state income assistance programs, were the poorest and most likely to be single with dependent children. Thus, they were most at risk for inadequate prenatal care and adverse outcomes. For instance, these women were at highest risk for low birthweight. However, even in this high-risk group the odds of inadequate prenatal care approached those for women receiving income assistance in British Columbia. This suggests that a substantial amount of the difference in the risk of inadequate prenatal care for this group may not be due to insurance-related barriers but rather to other social and structural factors related to poverty.

The primary limitation of this study is the use of different data sources for the determination of the adequacy of prenatal care in Washington and British Columbia. In Washington we used data obtained from patients or medical records and recorded on birth certificates, whereas in British Columbia, we used claims data to calculate the timing of the first prenatal visit and the total number of visits. Although claims data in Canada have been shown to be an accurate source of utilization data,[19] the linkage of all prenatal services may have been incomplete. Thus, recall bias in Washington and ascertainment bias in British Columbia limit the direct comparison of the proportions of inadequate prenatal care across regions. However, the differential effect of bias is minimized by comparing the relative differences in the adequacy of care between subgroups within each region.

The utilization of prenatal care may be affected by additional factors such as maternal education. Data on maternal education were not available from our data sources. However, data from other sources suggest that among women of childbearing age, the educational disparity between the poor and the more affluent is greater in the United States than in Canada.[20,21] If we extrapolate this observation to the maternal population, controlling for education in our analysis would likely further reduce differences in the risk of inadequate prenatal care among the poor between Washington State and British Columbia.

Differences in the regional organization of prenatal care services may also affect our results. The predominant difference between the two regions is the presence of managed care in Washington (12% of deliveries). However, health maintenance organization status was not a significant confounding factor in the relationship between Medicaid status and prenatal care use. Importantly, the distribution of deliveries by poor women and episodes of low birthweight across hospitals was similar in the two regions, indicating a similar level of regionalization of care.

Although the Medicaid program has clearly improved the process and outcome of prenatal care among the poor, the discouraging results of initial Medicaid expansion efforts have led to critical questions regarding the best strategies for making further gains. Current policy initiatives favor the gradual dissolution of the Medicaid program. Poor persons would be sponsored by government and combined with others into regional health insurance purchasing groups. With Canada as a benchmark, our findings suggest that such a strategy would greatly reduce the current disparity in the utilization of prenatal care between the poor and the more affluent. However, the gap in low birthweight appears to be resistant to the removal of insurance-related barriers alone. Clearly, targeted interventions that address social factors will be necessary to address this problem. Finally, the difference in the adequacy of prenatal care and birth outcomes between the poor and the more affluent in British Columbia may represent a minimum difference that could be expected if all economic and structural barriers related to health insurance were eliminated in the United States. □

Call for Abstracts for the National Primary Care Nurse Practitioner Symposium

The 20th National Primary Care Nurse Practitioner Symposium will be held July 20–23, 1995, in Keystone, Colo, and is sponsored by the University of Colorado Health Sciences Center School of Nursing. The theme is "A Legacy of Leadership: NPs Defining the Future."

Abstracts of research, innovative clinical practice/models and roles, and other professional papers relating to primary health care nursing are solicited. Preference will be given to abstracts with strong clinical applicability, innovative role development/practice models, and papers with a future-oriented perspective. Abstracts are being accepted for oral or poster presentation.

The guidelines for submission are the following:

- Send three typed copies of the abstract, limited to one page (300 words or less), single spaced, with 1½" left and 1" right margins. One copy, which will be printed in the syllabus if accepted, should include author name and contact information. The other two should have no author identification. Abstracts must include title and be photocopy-ready (do not use a dot matrix printer).
- Include author vita with author contact information.
- Format includes title, brief statement of purpose, methods, conclusions, and clinical application(s) or, if not a research abstract, brief summary of project/paper.
- Indicate interest in oral presentation and/or poster session.
- Presenters are provided tuition waiver for registration the day of their presentation, but they are responsible for their own travel and expenses.

Submission deadline is *September 15, 1994.* Contact Ellen Lemberg, RNC, MS, Nurse Practitioner Symposium Office, University of Colorado Health Sciences Center School of Nursing, 4200 E 9th Ave, Box C287, Denver, CO 80262; tel (303) 270-7436; fax (303) 270-3785.

Public Health Briefs

Smoking and Mortality among Residents of a California Retirement Community

ABSTRACT

Smoking cessation decreases mortality among the elderly. Participants in the Leisure World Cohort Study initiated in 1981 were followed until death or January 1, 1991. The 8869 women and 4999 men (median age = 73 years at initial survey) contributed 105 952 person-years of follow-up; 4002 had died. All-cause mortality rates were highest among current smokers; compared with never smokers the age-adjusted relative risks (and 95% confidence intervals) were 1.67 (1.46, 1.92) for women and 1.95 (1.66, 2.30) for men. Current smokers had increased risks of coronary heart disease, other cardiovascular disease, and cancer. Risk of death from smoking-related cancers continued to be high among former smokers, although lower than the risk among current smokers. Relative risks of mortality from cancer and cardiovascular disease increased with the number of cigarettes smoked per day and with a decreasing number of years since cessation of smoking. (*Am J Public Health.* 1994;84:992–995)

Annlia Paganini-Hill, PhD, and Grace Hsu, MS

Introduction

Although cigarette smoking causes coronary heart disease and cancer in middle age, few studies have examined the effect of continued smoking among those who survive to old age.[1-3] LaCroix et al. found that smokers' mortality rates were twice those of never smokers in a prospective study of 7178 persons aged 65 years or older.[1] Current smokers had higher rates of both cardiovascular and cancer mortality. Similarly, the Honolulu Heart Study found that smokers continued to have an increased risk of heart disease in older age.[2] However, the Framingham Heart Study reported no relation between smoking and mortality after 30 years of follow-up.[3] We evaluated the effect of smoking in a population-based cohort comprising a large number of people older than 75 years (including many women) and followed prospectively for 9½ years.

Methods

In June 1981, a health survey was mailed to all residents of Leisure World, Laguna Hills, a retirement community near Los Angeles, Calif. Residents moving into the community after this date were mailed this questionnaire in June 1982, June 1983, and October 1985. Residents are primarily White, affluent, well educated, and female (two thirds). The residents' median age at initial survey was 73 years. Of the 22 781 residents, 13 981 (61%), including 8879 women, returned questionnaires. Details of the study have been reported previously.[4,5]

The health survey requested information on life-style practices including use of cigarettes. Smoking status was classified as *current, past,* or *never* based on response to the question, "Have you *ever* smoked cigarettes during any period of your life (aside from possibly trying them once or twice)?" Current and past smokers were asked, "What is the greatest number of cigarettes that you have regularly smoked?" with the choices of *¼, ½, 1, 1½,* and *2 or more packs per day.* Current and past smokers were also asked, "At what age did you start smoking regularly?" Past smokers were asked, "At what age did you last stop?"

Cohort members were followed until death or January 1, 1991. Twenty cohort members were lost to follow-up; a search of the National Death Index did not reveal that these individuals were deceased. Cause of death as recorded on the death certificates was coded by using the *International Classification of Diseases,* Ninth Revision (ICD-9).

We evaluated the relation of smoking to mortality from all causes and from selected specific causes: coronary heart disease (ICD-9 codes 410–414); other cardiovascular disease (codes 390–405, 415–459, and 798); total cardiovascular disease (codes 390–459 and 798); smoking-related cancers (codes 141–145, 150, 157, 161, 162, 188, and 189), that is, cancers of the lung, trachea, bronchus, oral cavity, larynx, esophagus, pancreas, bladder, and kidney; and all cancers (codes 140–208).

Age-adjusted relative risks, with five age groups (≤ 74, 75–79, 80–84, 85–89, and 90+ years), and two-sided *P* values

The authors are with the Department of Preventive Medicine, University of Southern California School of Medicine, Los Angeles, Calif.

This paper was accepted September 30, 1993.

were obtained by using a regression method that assumed that the occurrence of death could be regarded as a Poisson process with a constant hazard rate for a given person.[6,7] The GLIM statistical software package program was used to make these calculations.[8]

Results

The 8869 women and 4999 men providing information on smoking contributed 105 952 person-years of follow-up (70 309 for women and 35 643 for men). Deaths occurred in 1987 women and 2015 men. More women than men were current smokers at baseline (12% vs 9%), and the prevalence of smoking decreased with age in both sexes (Table 1). Age-adjusted relative risks of specific causes of death by various smoking categories are shown in Tables 2 and 3 for women and men, respectively.

Mortality rates from all causes were nearly double among current smokers compared with never smokers. The age-adjusted relative risk of total mortality was 1.67 (95% confidence interval [CI] = 1.46, 1.92) in women and 1.95 (CI = 1.66, 2.30) in men. The relative risks for current smokers were increased in each age group (≤74, 75–79, 80–84, 85–89, and 90+ years) except for men aged 90 years or older (2.08, 1.83, 1.55, 1.26, and 1.59 for women and 2.09, 1.45, 2.09, 1.63, and 0.50 for men). Both female and male former smokers had rates of total mortality between those of current smokers and never smokers; the age-adjusted relative risk was 1.20 (CI = 1.09, 1.33) for women and 1.24 (CI = 1.13, 1.37) for men.

The higher risk of death among current smokers was because of deaths from cardiovascular disease and cancer.

[a]Person-years do not always total 35 643 because of missing values for some persons.
[b]Reference category for all relative risks.
[c]*P* values for test for linear trend are given unless test for deviation from linearity was significant ($P < .05$).

The age-adjusted relative risks for all cardiovascular disease for current smokers were 60% greater than those of never smokers: 1.68 (CI = 1.38, 2.05) for women and 1.60 (CI = 1.27, 2.02) for men. This increased risk was observed for mortality from coronary heart disease and from other cardiovascular disease. No elevation in the rate of all cardiovascular disease was observed among male former smokers, although the rate in female former smokers was increased.

The rates of death from all cancers were higher among the current smokers than among the never smokers. The age-adjusted relative risk was 1.65 (CI = 1.27, 2.14) for women and 2.74 (CI = 2.01, 3.74) for men. Current smokers had especially high rates of mortality from smoking-related cancers compared with never smokers. The age-adjusted relative risk was 3.70 (CI = 2.41, 5.67) for women and 6.39 (CI = 3.83, 10.6) for men. The risk of death from smoking-related cancers continued to be high among former smokers, although it was lower than the risk among current smokers. The age-adjusted relative risks for former smokers were 1.51 (CI = 1.01, 2.25) and 2.45 (CI = 1.62, 3.71) for women and men, respectively.

Risks of death from cancer and cardiovascular disease increased with the number of cigarettes smoked per day in both sexes. Less consistent trends were observed for the number of years of smoking. Former smokers who quit smoking more than 20 years ago had rates of death similar to those among never smokers for each specific cause except cancer in men, the risk for which remained high. In all cases the risk of death increased with decreasing number of years since cessation of smoking. Likewise, for all causes of death and each cause-specific category, the relative risk of death was higher among those who quit smoking at age 65 years or later than it was among those who quit before age 65.

Discussion

Previous reports concerning middle-aged populations have linked current smoking to mortality from coronary disease and cancer. However, few studies have evaluated the association between smoking and mortality in people older than 65 years, and only one has had a substantial number of subjects older than 75 years of age. Our findings suggest that the increased risks associated with smoking extend to groups beyond age 75. This agrees with the recent report by LaCroix et al.,[1] who found a marginally significant increased risk of death among smokers in that age group.

Previously, we found little evidence of response bias in this cohort when comparing early and late respondents on most variables.[9] In terms of illness (hypertension, angina, myocardial infarction, stroke, diabetes, rheumatoid arthritis, glaucoma, and cancer), we found no large differences between early and late respon-

dents. As with other surveys, we found that current smokers were slower to respond and former smokers were faster to respond than never smokers. However, the differences were not large. Nonetheless, systematic differences between early and late responders and the slightly higher incidence of hospitalizations during the first year of study among nonrespondents indicate that the early respondents are the "worried well," i.e., healthy individuals who see their doctor regularly, receive disease detection screening, and follow healthful life-style practices. However, using internal standards for comparing mortality rates, as we did, is unlikely to produce biased results.

The findings of this study support the efforts toward smoking cessation. Cancer and cardiovascular disease are essentially diseases of older persons, and the positive effects of smoking cessation on these diseases extend to old age. In view of the finding that former smokers who quit less than 20 years ago remain at increased risk of death, smoking cessation should begin early to reduce the risks of cardiovascular and cancer mortality and increase the health of older adults. □

The Utility of HMO Data for the Surveillance of Chronic Diseases

David L. Nordstrom, MS, MPH, Patrick L. Remington, MD, MPH, and Peter M. Layde, MD, MSc

ABSTRACT

In an area served by a single medical center that operates as both health maintenance organization (HMO) and fee-for-service clinic, we reviewed existing computerized medical records to determine the prevalence of 11 diseases. Standardized medical care utilization prevalence ratios, comparing the annual prevalences in the two groups, varied from 1.38 for rheumatoid arthritis to 0.60 for liver cirrhosis. Unless supplemented by data from hospitals, physicians, and other sources, HMO data may result in invalid estimates of the prevalence of chronic disease. (*Am J Public Health.* 1994;84:995–997)

Introduction

Surveillance of disease is the continuing scrutiny of all aspects of occurrence and spread of a disease that are pertinent to effective control.[1] Because in the United States chronic diseases account for a majority of deaths,[2] the Centers for Disease Control and Prevention are evaluating improved methods of surveillance.[3]

Traditionally, surveillance of chronic diseases has been done by using mortality data.[4] Although some registries track nonfatal cancer, cardiovascular disease, stroke, birth defects, trauma, and other noninfectious conditions,[5] few have employed routinely collected morbidity data from hospital discharge, health maintenance organization (HMO), or ambulatory care records.

Several characteristics of HMOs make them attractive for research, especially the existence of an identified and relatively stable population.[6,7] Yet examples of the use of clinical databases to relate the experience of the HMO population to epidemiologic trends are limited.[8,9] Studies of HMO populations are relatively recent.[10] No studies address the validity of such research, particularly with respect to disease surveillance.

TABLE 1—Standardized Prevalence of Medical Care Utilization, by Disease and HMO Status, Marshfield Epidemiologic Study Area, 1986 through 1988

Disease	Rate per 10 000 Person-Years (No. of Cases)	
	HMO	Non-HMO
Rheumatoid arthritis	40.1 (519)	29.1 (185)
Breast cancer	67.9 (490)	53.2 (166)
Myocardial infarction	201.9 (2917)	165.4 (1051)
Colorectal cancer	17.1 (252)	15.0 (95)
Stroke	62.3 (922)	55.2 (351)
Diabetes	197.2 (2604)	188.1 (1195)
Chronic lung disease	117.1 (1650)	115.1 (731)
Epilepsy	63.9 (527)	76.8 (488)
Cervical cancer	8.7 (39)	11.5 (36)
Lung cancer	8.1 (118)	11.0 (70)
Cirrhosis of liver	3.4 (49)	5.7 (36)

Note. Listed in descending order of prevalence ratios, as shown in Table 2.

TABLE 2—Standardized Prevalence Ratios of Medical Care Utilization for Selected Diseases: HMO Members Compared with Non-HMO Members, by Sex, Marshfield Epidemiologic Study Area, 1986 through 1988

Disease	Males		Females		Total	
	SPR	95% CI	SPR	95% CI	SPR	95% CI
Rheumatoid arthritis	1.73	1.36, 2.20	1.25	1.02, 1.54	1.38	1.16, 1.64
Breast cancer	. . .	. . .	1.28	1.06, 1.53	. . .	. . .
Myocardial infarction	1.46	1.31, 1.61	0.95	0.85, 1.05	1.22	1.14, 1.31
Colorectal cancer	1.16	0.82, 1.63	1.13	0.81, 1.59	1.15	0.90, 1.46
Stroke	1.18	0.98, 1.41	1.08	0.90, 1.28	1.13	1.00, 1.28
Diabetes	1.34	1.22, 1.48	0.84	0.76, 0.92	1.05	0.98, 1.13
Chronic lung disease	1.10	0.96, 1.26	0.88	0.75, 1.02	1.02	0.93, 1.11
Epilepsy	0.84	0.70, 1.00	0.83	0.69, 0.99	0.83	0.73, 0.95
Cervical cancer	. . .	. . .	0.76	0.47, 1.22	. . .	. . .
Lung cancer	0.67	0.41, 1.11	0.89	0.52, 1.51	0.74	0.54, 1.00
Cirrhosis of liver	0.57	0.30, 1.10	0.64	0.33, 1.22	0.60	0.38, 0.95

Note. SPR = age-standardized prevalence ratio; CI = confidence interval. Ratios are listed in descending order.

and hospital maintain a combined paper and computerized medical record on all patients.

The Marshfield Epidemiologic Study Area comprises 12 postal (zip code) areas joined for epidemiologic, clinical, and health services studies.[11] Apart from race and ethnicity, population characteristics of the study area and the United States are similar.[12]

Virtually all primary, secondary, and tertiary medical care to residents of this nonmetropolitan area is provided by Marshfield Clinic. An estimated 79% of residents sought care at Marshfield Clinic at least once during 1987. More than 92% of all hospitalizations of residents in 1986 were at Saint Joseph's Hospital.[13] The clinic operates the only HMO in the Marshfield Epidemiologic Study Area, and the clinic, HMO, and hospital are all served by a single, salaried medical staff.

From the Marshfield database, we have clinical information on non-HMO as well as HMO patients. To estimate disease occurrence on the basis of medical care utilization, in 1989 we obtained a computerized file of all patients whose current address was then in the Marshfield Epidemiologic Study Area and who had a medical diagnosis of 1 or more of 11 conditions during 1986 through 1988. Both new and old cases of active disease were included.

The file contained several diagnostic records for the same condition for many patients. To calculate annual prevalence of health care utilization for each of the diseases, we eliminated duplicate diagnoses of the same condition.

Population Estimates

To estimate the size of the area population by age and sex for the years 1986 through 1988, we modified zip code–specific population projections for 1989 from a commercial demographics firm.[14] We subtracted age- and sex-specific counts of HMO enrollees in the study area from these figures to derive estimates of the non-HMO population. We calculated disease-specific annual prevalence rates of medical care utilization by payment status, age, and sex. The age and sex distribution of the area population was used to standardize the rates for age and sex by the direct method.[15] We also computed standardized utilization prevalence ratios, analogous to standardized rate ratios, and their 95% confidence intervals.[16]

Results

From 1986 through 1988 the Marshfield Epidemiologic Study Area had an average total population of 47 606, including 26 427 HMO enrollees (56%) and 21 179 non-HMO enrollees (44%). Prevalence of medical care utilization ranged from a low of 3.4 per 10 000 person-years for liver cirrhosis to a high of 201.9 per 10 000 person-years for myocardial infarction (Table 1).

HMO enrollees had significantly higher rates of rheumatoid arthritis, breast cancer, and myocardial infarction than the non-HMO group (Table 2). Conversely, rates of epilepsy and cirrhosis of the liver were significantly lower in the HMO group. In addition, although male HMO enrollees had a significantly higher prevalence of diabetes than nonenrollees, female HMO enrollees had a significantly lower prevalence.

Discussion

Valid disease incidence and prevalence rates are obtainable from a clinical database only if it is population based.[17] This study reports such data from a new epidemiologic laboratory in a rural area served virtually exclusively by a single medical center.

Some of the differences in the patterns of medical care utilization for

specific diseases may be due to selection of HMO coverage by individuals with underlying conditions, such as arthritis, that put them at risk. The differences in the prevalence of medical care utilization for other diseases, however, may reflect different proportions of risk factors, such as alcohol consumption, in the HMO and non-HMO populations.

In addition, some study area residents may travel elsewhere for medical care. If fewer than 10% of the non-HMO enrollees are obtaining their care elsewhere, then our calculations would overestimate the prevalence ratio by less than 9%. There is also potential for error in transcription or extraction from medical records[18,19] and in entering or retrieving information from the computerized database.

The Institute of Medicine recommends that every public health agency regularly and systematically collect, assemble, analyze, and make available information on the health of the community.[20] We encourage physicians and public health officials to incorporate HMO surveillance into their chronic disease control programs on a trial basis. That will permit a balanced assessment of the strengths of HMO data—such as their widespread availability, relative economy, and rich clinical detail—in comparison with their potential weaknesses. □

Popular Films Do Not Reflect Current Tobacco Use

Anna Russo Hazan, PhD, MPH, Helene Levens Lipton, PhD, and Stanton A. Glantz, PhD

ABSTRACT

This study examined trends in tobacco use in a random sample of 2 of the 20 top-grossing US films each year from 1960 through 1990 (62 films). The overall rate of tobacco use did not change. Films continue to portray smokers as successful, attractive White males. Smoking groups became larger, smoking alone declined, hostility and stress reduction were increasingly associated with smoking, and smoking by minor characters increased. Although smoking among elite characters fell, it remained nearly three times as prevalent as in actual population data during the 3 decades. Events involving young people more than doubled. Films do not accurately represent smoking in the United States. (*Am J Public Health*. 1994;84:998–1000)

Introduction

Movies both shape and reflect social values regarding tobacco use. The public believes that there is less smoking than before in movies in the last 5 years.[1] We investigated whether this perception is accurate by studying tobacco use in popular films since 1960.

Methods

Sample Selection

Two feature-length films on videocassette for each year from 1960 through 1990 were randomly selected from the 20 top money-making films each year[2] (62 films). Eight films (13%) were not available on videocassette and were replaced at random with another film from the same year. (Of these eight films, half were from the Disney corporation, which holds back certain films from the video market as a sales strategy.[3])

Data Collection

The title, year of release, rating (G, PG, PG13, R, or X), genre,[4] target audience, and historical era of each of the selected films were recorded. (Ratings for age suitability did not occur until 1968, when the current system was instituted by The Motion Picture Producers and Distributors of America.[5] Films released before 1968 [26%] were unrated. Of the remaining 46 films, 33% [15] were rated G, 52% [24] were rated PG or PG13 [parental guidance suggested], and 15% [7] were rated R [under age 17 not admitted without adult companion]. No X rated [under age 17 not admitted] films appeared in the sample.) The presence of tobacco events in each 5-minute interval of film time was documented upon viewing each videocassette. "Tobacco events" included implied or actual consumption of tobacco, paraphernalia, (ashtrays and matches), talking about tobacco, "no smoking" signs, and tobacco product logos. A per-film reliability ratio of .92 (SD = .07) was computed by comparing the consistency of observations between two coders who viewed the same 15 films independently.

To document tobacco events within each 5-minute interval, 25 variables were coded for every event, including smoker characteristics (e.g., age, sex, role), tobacco characteristics (e.g., product, brand names, tobacco paraphernalia), and scene characteristics (e.g., number of smokers, health messages). Smokers' characteristics were coded when an individual participated in actual smoking or when there was a clear intention to smoke. Intent to smoke was grouped with actual smoking in the analysis, as in prior studies.[6] When only paraphernalia or nonsmoking events were involved, no smoker characteristics were coded.

Statistical Methods

We examined the rate per minute of film at which tobacco events occurred by generating 149 variables from different responses to the original 25 variables (codes and categories of variables are available on request). This rate equaled the total number of times an event occurred divided by the length of the film. Rates were computed because films became shorter by 0.8 minutes per year over the 31-year study period ($P < .01$ by linear regression). We tested for changes over time in the rates of these tobacco events by computing Spearman rank order correlations between the tobacco event rates occurring in each film and the year of release. (The unit of analysis was the film.)

To test for changes decade to decade, we evaluated the characteristics of each film using the original set of 25 variables and cross tabulated the frequency with which each of these characteristics appeared by the decade in which the film was released (1990 was considered

At the time of the study, the authors were with the Institute for Health Policy Studies, Department of Medicine, University of California, San Francisco. Dr Russo Hazan died after the study was completed.

This paper was accepted September 23, 1993.

part of the decade of the 1980s); we then analyzed the resulting two-way contingency tables with chi-square tests. (The unit of analysis was the tobacco event.)

Results

The 62 films contained a total of 1505 five-minute intervals (an average of 24.3 intervals per film). Of the 1505 intervals, 36% contained some reference to tobacco; 785 tobacco-related events were recorded for analysis. Tobacco was present and used in 78% (611) of these events and implied in the remaining 22%.

There was virtually no change in the presence of tobacco over time. Of the 149 variables correlated with time, 17 showed significant changes, a number not much more than expected by chance (with $\alpha = .05$).

The motivation of the smoker changed when analyzed by the 3 decades ($P = .03$). Relaxation was the dominant motive (38%, 27%, and 38% in the 1960s, 1970s, and 1980s), respectively. Relaxation motivations included rites of passage (teenage party smoking), ritual (automatic) smoking, and pensive moments.

Thirty-eight percent of tobacco events involved major characters in the 1960s, in comparison with 29% in the 1970s and 26% in the 1980s ($P = .02$). Over the decades, ethnicity changed ($P < .01$). Fewer smoking events involved Whites (81% vs 80% vs 72%), and more involved African Americans (1% vs 4% vs 4%). Gender also changed ($P < .01$). Fewer events involved males (72% vs 79% vs 65%), and more involved females (11% vs 5% vs 15%). Tobacco events involving relatively young people (aged 18 to 29 years) more than doubled (21% vs 22% vs 45%), while the next older group (30 to 45 years) fell by nearly half (39% vs 33% vs 21%) ($P < .01$).

Occasionally (7% of tobacco-related events), smoking was held in contempt, mostly expressed as ridicule. Talk about tobacco was generally positive and inferred pleasure in the act (3% of events over time). These patterns did not change over time.

The size of the group involved in the tobacco events changed, with less smoking in small groups (1 or 2 people) and more in larger groups (16 or more people) ($P < .01$). There was a change in interaction quality ($P < .01$). Congenial interactions declined, and hostile situations increased. There was a small but statistically significant change in the presence of health messages over the decades (2% vs 1% vs 4%) ($P = .05$). Business activities (36%) consistently were the most popular smoking context, while smoking alone declined significantly (13% vs 9% vs 4%) ($P < .01$).

Some smoking behaviors varied over the decades. For example, the smoking level for those 46 to 60 years of age increased from the 1960s (41%) to the 1970s (45%) but decreased in the 1980s (34%) ($P < .01$). This same phenomenon was true for group size "over 16" (15% vs 23% vs 12%) ($P < .01$). Social contexts and motivation showed similar patterns.

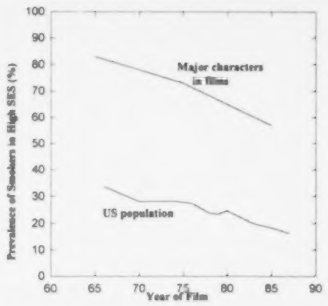
Although the overall rate of smoking was stable over the 3 decades, the prevalence among major elite characters fell over time. Smoking among elites, however, remained nearly three times as prevalent as in the actual population (57% vs 19% in the 1980s) (Figure 1).

Discussion

Films present a smoker who is typically White, male, middle class, successful, and attractive, a movie hero who takes smoking for granted. As in tobacco advertising, smoking in the movies is associated with youthful vigor, good health, good looks, and personal/professional acceptance.[7] There was no significant decline in overall tobacco use over the years 1960 through 1990, but changes in tobacco presentation were found. Smoking became less personal and more social, suggesting that smoking had more populist appeal. There was an increase in the amount of hostility associated with smoking, which may be attributed to the increase in violence in films and the popularity of the antihero. Smoking was used as an anxiolytic, reinforcing its "healthful" properties as a stress reducer, a finding consistent with tobacco industry efforts to promote tobacco use as an alternative intervention to improve mental health.[6]

To some extent, the movies included in this study reflected the reality that better educated, more affluent groups were smoking less over time. While the prevalence of smoking among major characters with high socioeconomic status has decreased, it is still almost three times as prevalent as in comparable population members and has always represented a majority behavior. Another measure of changing social expectations was that ashtrays almost disappeared from movies. The surgeon general has observed that the "ashtray is following the spittoon into oblivion."[8] Films have mirrored this observation. We observed a gradual, consistent decline in the presence of ashtrays (Figure 2).

Movie producers state that they lack established policies about using cigars or cigarettes in their productions other than the overall intention to stay truthful to the characters.[9] They may be using smoking as a means of enhancing the character of a figure, whereas previously, smoking was so prevalent that no such distinction could



Note. The percentage of major characters with high socioeconomic status (equivalent to college graduates based on their occupational status) was calculated and compared with the US population data on smoking by educational status.[8]

FIGURE 1—Smoking prevalence among high socioeconomic status (SES) major characters vs that of comparable members of the US population.

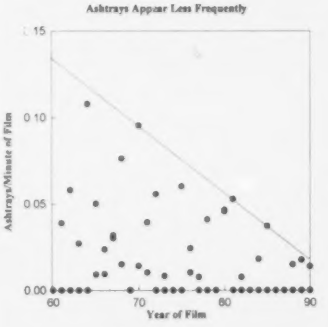


FIGURE 2—Rates at which ashtrays appeared through the period of the study.

be made. Nonetheless, films reinforce misleading images and overstate the normalcy of smoking, which may encourage children and teenagers, the major movie audience, to smoke. □

The Resurgence of Tuberculosis in New York City: A Mixed Hierarchically and Spatially Diffused Epidemic

Deborah Wallace, PhD

ABSTRACT

For New York City from 1978 to 1990, plotting the 3-year running averages of citywide new tuberculosis cases against the middle year yielded an S-shaped curve, with the inflection point at 1983 between early slow and late rapid rise. The inflection in the S curve appears to be associated with hierarchical establishment of secondary epicenters, and the phase of rapid rise in new cases seems to be associated with spatial diffusion from both the primary and secondary epicenters. (*Am J Public Health.* 1994;84:1000–1002)

Introduction

Beginning in the mid-1970s, tuberculosis in New York City edged out from under control as housing overcrowding and residential instability grew in the face of massive low-income housing destruction. This process and aspects of the epidemic that became manifest in 1979 have been described previously.[1]

Medical geographers have developed a taxonomy of contagious spread: hierarchical diffusion, spatial diffusion, and network diffusion.[2,3] Spatial diffusion is the simple geographic spread from an epicenter. Network diffusion refers to a spread via personal and business networks. Hierarchical diffusion is the hardest to understand: the spread from a major urban center where the disease has a very high incidence and prevalence to subordinate communities. The order of spread depends on both the frequency of comings and goings between the primary epicenter and the subordinate communities and the population and population densities of the subordinate communities.[2,3] Once established in these secondary epicenters, the disease spatially diffuses as from the primary epicenter. In this paper, the dynamics of the New York City tuberculosis resurgence are analyzed in light of hierarchical and spatial diffusion.

Materials and Methods

All tuberculosis data were taken from the annual reports of the New York City Tuberculosis Bureau. The bureau's reported new cases and incidences (new cases per 100 000 population) were used. The denominator for calculation of incidence was the last 10-year census population. For 1978 through 1990, the 3-year running averages of the annual new tuberculosis cases were plotted against the middle year of the 3 averaged years.

The following health districts were mapped by year from 1978 through 1990: the districts representing the top quintile for incidence (new cases per 100 000 population) and all other districts with an incidence above the 1978 citywide incidence. The number of cases per square mile was calculated for the top-quintile districts by year from 1978 through 1990 by dividing the number of new cases by the district area in square miles, as provided by the New York City Department of Health.

This paper was accepted November 12, 1993.

Results

The graph of the 3-year running average of total citywide new cases vs the middle year of the 3 averaged years shows a classical S shape with the inflection point at 1983 (Figure 1).

The geographic changes over time in incidence are important to analyze to delineate whether this 1982 through 1984 period has characteristics different from the preceding 1978 through 1981 period.

Figure 2 maps the districts of elevated incidence for 1978, 1982, and 1990. By 1982, districts in the top quintile had spread into Brooklyn and the Bronx, whereas in 1978, only one health district outside of Manhattan had ranked in the top quintile (Fort Greene in Brooklyn). These maps also show the spread in elevated incidence in relationship to the top-quintile districts. As the top-quintile districts became well established in both Brooklyn and the Bronx, more districts in these boroughs attained elevated incidence until, by 1990, the entire Bronx was above the 1978 citywide incidence, as were all health districts but one in Brooklyn.

Table 1 displays the number of new cases per square mile (new case density) for the top quintile by incidence rate and year. Although Manhattan routinely had district case densities of more than 25 new cases per square mile during each year of the study period, neither Brooklyn nor the Bronx had a single district with a case density of 25 per square mile or more until 1982. By 1984, both Brooklyn and the Bronx each regularly had at least one health district with 25 or more new cases per square mile. By 1990, five of the six

1989	**105.22 (CH)**	**63.79 (LE)**	*45.46 (Be)*	50.15 (Mo)	*38.86 (FG)*	17.24 (MH)
1990	**142.79 (CH)**	**88.83 (LE)**	**100.87 (EH)**	61.98 (Mo)	*54.75 (Be)*	*29.82 (Bu)*

Note. Manhattan districts appear in boldface, and Brooklyn districts appear in italics. The remaining districts are those of the Bronx. CH = Central Harlem, LE = Lower East Side, FG = Fort Greene, LW = Lower West Side, WH = Washington Heights, Ri = Riverside, Be = Bedford, EH = East Harlem, MH = Mott Haven, Mo = Morrisania, Bu = Bushwick.

top districts had new case densities above 50 per square mile. Top-quintile districts were established in Brooklyn and the Bronx at around the same time as very high spatial concentrations of new cases occurred. Until the Bronx and Brooklyn districts of Morrisania and Bedford reached the density of 25 new cases per mile per year, they did not show annual increases in new case density or incidence.

Discussion

Our benchmark year of 1978, the year of lowest citywide tuberculosis incidence, had remarkable characteristics: the top-ranking health district was not much higher in incidence than the second-ranking district and lay along the same line as the others in the rank vs incidence plot (D. Wallace, unpublished paper); all but one of the top-quintile districts were in Manhattan; and only five districts other than those in the top quintile exceeded the 1978 citywide average. Outside the top quintile, the health districts' new case densities were below 25 per square mile in 1978.

The 1982 through 1984 period formed the inflection of the plot of the 3-year running averages of new cases vs year as the pattern changed from small to large annual increases. The maps of the districts with elevated incidence show that 1982 through 1984 was a period marked by the first establishment of top-quintile districts in both Brooklyn and the Bronx. In addition, in 1982 and 1983, the Morrisania district's new case density rose above 25 per square mile and continued to rise; in 1984, a Brooklyn district, Bedford Stuyvesant, rose above the 25 new cases per square mile density and was joined in 1985 by Fort Greene. Thus, the inflection period features both the spread of the high-ranking incidence districts over three boroughs (instead of being highly concentrated in one) and centers of high case density in three boroughs instead of in one. By 1985, a full system of hierarchical and spatial diffusion had developed and underlay the exponential phase of the epidemic, the postinflection phase of large annual increments. Cliff et al.[2] clearly associated the S-shaped curve of the kind seen for the 3-year running averages with a mixed hierarchical/spatial diffusion. Here, a possible mechanism for the S shape is revealed: first, spatial diffusion from one or two major epicenters (slow early rise); second, hierarchical establishment of secondary epicenters (inflection phase); and third, spatial diffusion from both the primary and secondary epicenters (rapid postinflection rise).

Because a main epicenter and auxiliary epicenters were already established in 1985, control of the disease at the population level will be much more complicated than it would have been before 1982, when only the main epicenter determined the spread and rise of incidence and when housing overcrowding was at a more manageable level. In 1990, new case density in each of these secondary epicenters was above 50 cases per square mile (the case density of the Lower East Side and/or Central Harlem since 1979, when these two districts were the primary epicenters). The data here hint that 25 new cases per square mile is the functional threshold for a secondary epicenter outside of Manhattan and that the establishment of the hierarchical system with primary and secondary epicenters contributed to the change from a slow to a rapid increase in citywide annual new cases. □

Temporal Trends in the Socioeconomic Gradient for Breast Cancer Mortality among US Women

Diane K. Wagener, PhD, and Arthur Schatzkin, MD, DrPh

ABSTRACT

Temporal trends in breast cancer mortality among US women were examined for 1969 through 1989 by age, race, and county-level socioeconomic status (SES). The mortality ratio for high- relative to low-SES counties declined significantly among women 25 to 44, 45 to 64, and more than 65 years of age, respectively, from 1.13 to 0.96, 1.32 to 1.19, and 1.48 to 1.26. The narrowing of mortality occurred among Whites and, to a lesser extent, Blacks. A relative increase in either breast cancer incidence among women in lower SES counties or improved survival among women in higher SES counties (reflecting greater use of screening and treatment) could account for this relative worsening of breast cancer mortality among lower SES women in lower SES counties. (*Am J Public Health.* 1994;84:1003–1006)

Introduction

Breast cancer kills more than 175 000 women throughout the world each year.[1] Among women in the United States, this malignancy accounted for an estimated 46 300 deaths in 1992.[2] Breast cancer mortality, in contrast to most other causes of death,[3] is greater among women having higher, as compared with lower, socioeconomic status (SES).[4,5]

Death statistics in the United States are routinely reported by gender and age but not by SES. Little is known, therefore, about how breast cancer mortality in this country has changed over time for women in different social classes. Because a woman's SES reflects to some degree her risk behaviors and exposure to possible carcinogens,[3–8] as well as her use of screening and treatment services,[3,8–10] investigation of mortality trends by SES may be valuable. In this paper, county-level data are used to examine the relation of SES indicators to breast cancer mortality over the last 2 decades among Black and White women in the United States.

Methods

County socioeconomic data (median family income and percentage of persons 25 years of age or older with at least a high school education) were obtained from the Area Resource File[11] for both the 1970 and 1980 census years. Other studies of breast cancer incidence[4,12–14] and mortality[6] have used these census-based socioeconomic indicators with regions ranging in size from census tract (or block groups) to the county level. Counties (n = 3075) were assigned to quintiles based on the rank of the value for each variable (Table 1). Because less than 15% of the population lived in the two lowest quintile counties, these quintiles were combined to minimize the variance of the ratio estimates.

County-based mortality data, obtained from the Compressed Mortality File,[15–17] were available on Whites separately for 1968 through 1989 and on Blacks separately for 1979 through 1989. Population estimates provided by the National Cancer Institute and death records obtained from the detailed mortality files of the National Center for Health Statistics were used to obtain data for Blacks in 1969 through 1972. Deaths of women 25 years of age or older with an *International Classification of Diseases* (ICD), Eighth Revision (adapted) or Ninth Revision, code of 174 were selected.

Data were combined over several pericensal years. Because the ICD version changed between 1978 and 1979, four (rather than five) pericensal years were combined (i.e., 1969 through 1972 and 1979 through 1982). Also, data from the most recent years (1987 through 1989) were combined.

Data from both files were merged (e.g., 1969 through 1972 deaths and population data were combined with the 1970 SES variables). Because county-level 1990 SES data were not yet available, the 1987 through 1989 mortality data were combined with 1980 SES data.

Statistics include age-specific rates (total number of age-specific deaths over the time period divided by total age-specific person-years); age-adjusted death rates (adjusted to the 1970 US age distribution[18]); standard errors or 95% confidence intervals (CIs) for rates and ratios[18]; and significance of trends of risk ratios.[19]

Results

Breast cancer mortality among US women aged 25 and over rose 3.0% from 1969 through 1972 to 1987 through 1989

[a]The poverty level for a family of four was $3743 in 1969 and $7412 in 1979.

TABLE 2—Breast Cancer Mortality Rates among US Women, by Age and Race

Race/Age, y	Rate (95% Confidence Interval) 1969–1972	1979–1982	1987–1989
White			
All adults	49.6 (49.3, 49.9)	49.4 (49.1, 49.7)	50.7 (50.4, 51.0)
25–44	11.1 (10.9, 11.3)	9.8 (9.6, 10.0)	9.5 (9.3, 9.7)
45–64	64.4 (63.8, 64.9)	62.2 (61.7, 62.7)	61.1 (60.5, 61.7)
65+	110.9 (109.9, 111.9)	117.1 (116.2, 118.0)	127.2 (126.2, 128.2)
Black			
All adults	43.7 (42.8, 44.6)	49.5 (48.7, 50.3)	56.7 (55.7, 57.7)
25–44	13.1 (12 5, 13.7)	13.9 (13.3, 14.5)	15.9 (15.2, 16.6)
45–64	53.5 (51.9, 55.1)	65.8 (64.2, 67.4)	74.0 (72.1, 75.9)
65+	76.8 (73.9, 79.7)	100.8 (98.0, 103.6)	118.5 (115.3, 121.7)
All			
All adults	49.2 (48.9, 49.5)	49.0 (48.7, 49.3)	50.7 (50.4, 51.0)
25–44	11.5 (11.3, 11.7)	10.2 (10.0, 10.4)	10.1 (9.9, 10.3)
45–64	63.8 (63.3, 64.3)	62.0 (61.5, 62.5)	61.6 (61.0, 62.2)
65+	108.8 (107.9, 109.7)	114.9 (114.1, 115.7)	125.2 (124.5, 126.1)

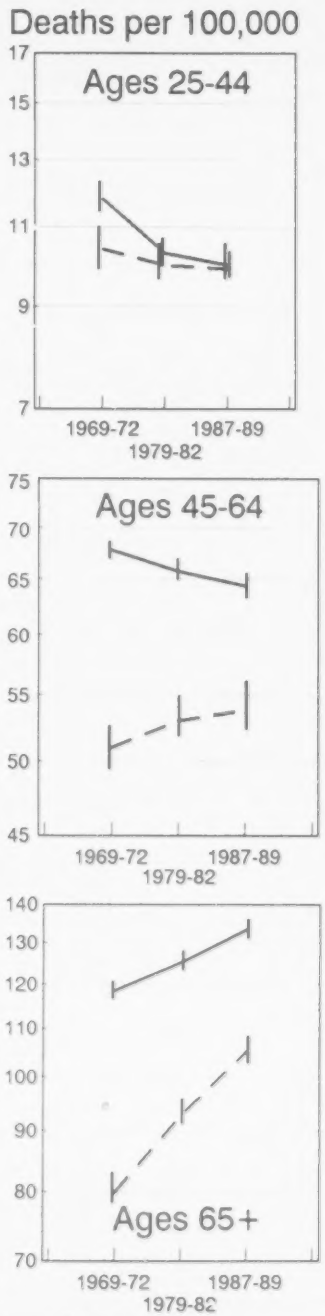
Note. Mortality rates are per 100 000 women. Mortality was age-adjusted to the 1970 US population.

(Table 2). Different trends are evident if the death statistics are broken down by age and race. Among Black women, mortality climbed 21.4% for those 25 to 44 years of age, 38.3% for those 45 to 64, and 54.3% for those over 64. Among Whites, mortality declined 14.4% among younger women and 5.1% among middle-aged women but increased 14.7% among older women.

The relative worsening of mortality for Blacks is reflected in trends for the Black–White mortality ratio. In the interval from 1969 through 1972 to 1987 through 1989, this ratio increased from 1.18 (95% CI = 1.12, 1.24) to 1.67 (95% CI = 1.59, 1.75) for women aged 25 to 44 years, from 0.83 (95% CI = 0.80, 0.86) to 1.21 (95% CI = 1.18, 1.24) for women 45 to 64, and from 0.69 (95% CI = 0.66, 0.72) to 0.93 (95% CI = 0.90, 0.95) for women 65 or older.

Figure 1 depicts breast cancer mortality trends among quintiles defined by county median family income for all races combined (see also Table 3). Despite the opposite trends of mortality in younger and older women, the SES differentials narrowed for both age groups. The SES differential also narrowed among middle-aged women. Education quintiles provide similar but slightly attenuated results both within time periods and over time (data are available from the authors on request).

Table 3 also presents, race, age-, income-, and time period–specific mortality as well as ratios of mortality among the



Lowest Quintiles (1 and 2) - - - -
Highest Quintile (5) ——
Note. Mortality rates (and confidence intervals, shown as vertical bars) are shown for 1969–1972, 1979–1982, and 1987–1989 among women 25–44 years old, 45–64 years old, and 65 years old or older. Death rates were age-adjusted to the 1970 US population.

FIGURE 1—Breast cancer mortality, by quintile of median family income (multiyear averages).

highest quintile populations and the two lowest quintile populations. Among Whites, all of the changes in ratios were significant. For Black women, the high–low mortality ratio was unchanged among the younger women and decreased somewhat for the other age groups, in part because of a substantial breast cancer mortality increase in the poorer counties.

Discussion

Our study shows a narrowing of the direct SES differential in the breast cancer gap over the past 2 decades among US women for each age and race group (except the youngest Black women). Breast cancer mortality, which has been rising among women 65 years of age and older, has increased more rapidly among those in lower SES counties. Among women 45 to 64, breast cancer mortality has been declining in those women in higher SES counties but rising in their lower SES counterparts. Finally, women 25 to 44 have experienced a fall in breast cancer death rates over the last 2 decades, with the decline being more rapid in those in higher SES counties. Earlier data (through 1971) from the United Kingdom suggest a similar shrinking of the social class gradient in breast cancer mortality.[7]

These analyses were areal (or "ecologic"). County-level SES may be a proxy for *individual-level* measures (e.g., income, education, and type of health insurance) or a reflection of *county-level* characteristics (e.g., population density, pollution, and availability of screening and treatment services). Indeed, there may be a mix of individual- and county-level factors at work. Further studies using census tracts or blocks or other areas smaller than the county for ascribing SES might reduce the classification error known to exist in ecologic analyses.[20–22]

Data from other studies suggest that these observed SES trends in breast cancer mortality can be explained by changes in both incidence and survival. Cross-sectional ecologic analyses by SES indicate that breast cancer incidence is greater among women of higher SES.[4,23] However, between 1974 and 1984, the incidence in the Seattle region increased more rapidly among women living in low-income census tracts.[14] Use of both mammography[9] and breast examination[9,10] has been shown to be lower and to have increased more slowly between 1974 and 1984 among poorer or less educated women in the United States. Cross-sectional data indicate that lower SES

Note. Mortality rates are per 100 000 women. Mortality was age-adjusted to the 1970 US population. Q5:Q1, 2 = rate ratio of mortality in highest income quintile (Q5) to population-based weighted average mortality of two lowest income quintiles (Q2 and Q1). Because of the nature of ratio estimates, the ratio for the total population is not a simple average of the ratios for each subpopulation. Trend = test for trend over time of ratios of Q5 to Q1 and Q2 (combined).

women present at a more advanced stage of disease.[24] Whether treatment differentials by SES play a role is unclear. Thus, the diminishing mortality gap over time among women living in high- as compared with low-SES counties may reflect (1) a more rapidly rising incidence of breast cancer among younger women in low-income counties or (2) greater survival among women in high- income, or poorer survival among women in low-income, counties.

Women in lower SES counties appear to be reaching "equity" in breast cancer mortality with those living in higher SES counties. This, unfortunately, is not the kind of SES equity one might hope for. Further investigations of temporal trends in the SES distribution of risk factors (for incidence and survival) might provide additional etiologic leads and direct attention to deficiencies in breast cancer medical services. This would benefit women from all social strata. □

Candidates Sought for Reproductive Health Initiative Awards

The American Medical Women's Association (AMWA) announces its first Reproductive Health Initiative Awards to recognize physicians who have made outstanding contributions to reproductive health for women. The $10 000 national award will be presented to a male or female physician who is a prominent and well-known current reproductive health care provider and who, in the view of AMWA, has made significant contributions to advancing women's reproductive health and has attempted to bring these issues into mainstream medicine.

AMWA will consider candidates who have dedicated personal time and their professional career to providing quality reproductive health care services, including abortion services. Potential awardees will be those who have provided leadership and education and who have promoted reproductive health issues on a national level.

The new award is part of AMWA's Reproductive Health Initiative, a 3-year project to develop and promote curricula that medical schools can use to train medical students in reproductive health. Interested medical schools can participate in the initiative training by holding 1-day seminars. In addition, AMWA will arrange for fourth-year medical students to be trained in reproductive health.

To be considered for the national award, those nominating potential candidates should provide a nomination statement between 50 and 250 words and send it with the nominee's curriculum vitae, nomination form, and other relevant supporting information to AMWA by *Friday, July 22, 1994.* For a national application, contact Susan Eisendrath, MPH, Project Coordinator–RHI, c/o AMWA, 801 N Fairfax St, Alexandria, VA 22314; tel (703) 838-0500.

Five local awards of $1000 each will be granted through AMWA branches. To be considered for a local award, contact AMWA for the name of the president of the branch in your area.

Racial Differences in Cervical Cancer Mortality in Chicago

Elizabeth J. Samelson, MPH, Marjorie A. Speers, PhD, Richard Ferguson, MS, and Charles Bennett, PhD

ABSTRACT

Racial differences in cervical cancer mortality in Chicago were examined. Age-adjusted mortality in Blacks (10.0/100 000) was over twice the rate found in Whites (4.6/100 000). Age-specific rates also showed significant excess mortality among Blacks. After stratification by a group-level defined poverty indicator, the race differential in age-adjusted rates remained significant. The race differential in age-specific rates diminished in the group with more than 30% living below the national poverty level, in contrast to the group with 30% or fewer living below the national poverty level, in whom race differences were more marked. Methodological issues concerning hysterectomy prevalence, Hispanic ethnicity, and social class must be considered with respect to interpretation of these findings. (*Am J Public Health.* 1994;84:1007–1009)

Introduction

Cancer of the cervix is one of the cancer sites most amenable to early detection and treatment, yet it is the second leading cause of cancer mortality for women worldwide[1] and ranks third among cancer deaths nationally for women aged 25 through 44 years.[2] Throughout the last decade, marked excess cervical cancer mortality in Blacks has persisted despite declining rates in both Black and White women.[3]

Chicago's mortality rates for cervical cancer deaths were 14% higher than national rates for Whites and 24% higher for non-Whites from 1968 through 1982.[4] The present study was conducted as part of a federally funded state health department program established to develop cervical cancer prevention strategies. The program was divided into three phases: descriptive epidemiologic research, analytic study, and finally, the design and implementation of a demonstration project. The present study was undertaken to provide a descriptive account of racial differences in cervical cancer mortality among women in Chicago.

Materials and Methods

The study area included 37 central Chicago communities (representing approximately 53% of Chicago's total population) selected from the 1980 census. The far northern and southern portions of Chicago were excluded to reduce the number of patients more likely to utilize suburban or out-of-state health facilities and to include a greater proportion of low-income and minority women.

Estimates of the female population residing in the study area were obtained from the 1980 census, the only available data specific for age, race, gender, and community area. Race was classified as White (including Hispanic) and non-White. Because 93% of the non-White group was Black, this term will be used throughout this report.

Deaths from cervical cancer (*International Classification of Diseases*, Ninth Revision, codes 180.0–180.9) were selected from the state of Illinois death tapes for the period from 1975 through 1984. Average annual mortality rates are presented. Information on poverty status was not available on an individual level for this study. Nevertheless, an effort was made to account for potential confounding by categorizing subjects, at the group level, according to the percentage of residents ($>30\%$, $\leq 30\%$) living below the national poverty level in the community area where each resided. Thirty percent was chosen as the value to dichotomize this poverty variable in order to minimize the number of cells with zero cases and to ensure a reasonable estimate of poverty in the community areas.

Age-standardized rates were calculated by the direct method[5] with the combined population of the 37 community areas as the standard. The z test (two tailed) based on the standard normal distribution was used for statistical testing of race differences in the age-specific rates[6] and the overall age-adjusted rates.[5] (Significance was defined at $P < .05$.) Rate ratios (and 95% confidence intervals [CIs]) comparing mortality in Blacks with that in Whites were calculated with DEPID.[7]

Results

From 1975 through 1984, 600 cervical cancer deaths were reported for the study

At the time of the study, Elizabeth J. Samelson was with the Cervical Cancer Demonstration and Control Project, Illinois Department of Public Health, Chicago, Ill; she is currently a doctoral student in epidemiology at Columbia University, New York, NY. Marjorie A. Speers is with the Division of Chronic Disease Control and Community Intervention, Centers for Disease Control and Prevention, Atlanta, Ga. At the time of the study Richard Ferguson was with the Illinois Department of Public Health; he is currently with the Cook County Bureau of Health Services, Chicago, Ill. Charles Bennett was with the Southern Illinois School of Medicine, Springfield, Ill; he is currently with the Vermont Department of Health, Burlington, Vt.

Crude rate	5.2	198	8.8	402	1.9	1.6, 2.1	1.6	1.3, 1.9	1.5	1.2, 1.9
Adjusted rate[d]	4.6		10.0		2.1	1.8, 2.5	1.7	1.2, 2.4	1.9	1.5, 2.4

[a]Rates per 100 000. Rates based on fewer than 5 cases were not calculated.
[b]White is reference group.
[c]Study area includes 37 geographically contiguous communities located in central Chicago selected from the 1980 census.
[d]Rates were age adjusted to the total study population by the direct method.

area (Table 1). Almost half the deaths (287) occurred among women younger than 55 years of age. The age-adjusted mortality rate of 10.0 for Black women was more than twice the overall rate of 4.6 for Whites ($P < .001$). A comparison of age-specific rates yielded similar results: Blacks had statistically significant greater mortality at every age level. Mortality rates for Black women were more than 2 times those for White women in the 15–34 and 35–54 age groups, 1.7 times those for White women in the 55–74 age group, and more than 3.5 times those for White women in the 75+ age group. Mortality rates increased significantly with age for both races, but the greatest increases occurred among Black women.

The race differential in the age-adjusted mortality rates remained statistically significant after stratifying by poverty group. The Black–White rate ratio was 1.7 (CI = 1.2, 2.4) for the >30% poverty group and 1.9 (CI = 1.5, 2.4) for the ≤30% poverty group (Table 1).

Within the community areas of ≤30% poverty, mortality was significantly greater in Blacks in all but the youngest age group (rates not shown). Although the rates for Blacks were greater than the rates for Whites at every age level in the >30% poverty group (rates not shown), none were statistically significant.

Discussion

The marked excess of cervical cancer deaths among Black women in Chicago described in this report is consistent with national data demonstrating more than a twofold increase in mortality rates for Black women.[3] Several methodological issues must be considered with respect to the interpretation of our findings.

The rates presented here included women with prior hysterectomies; consequently, mortality was underestimated in this study. The effect on the rate ratios is prohibitively complex to predict because of potential age, race, and socioeconomic differences in hysterectomy prevalence. Results from the Behavioral Risk Factor Surveillance System, however, did show that overall frequency of prior hysterectomy was the same for Whites, Blacks, and Hispanics in a national sample of women; lower income and less education, however, were related to increased prevalence of hysterectomy.[8]

A second limitation of this study concerns the validity of using census denominators to enumerate the Whites and non-Whites in the study population. Because information on ethnicity was not included in mortality data at the time of this analysis, rates for Hispanics could not be calculated separately from those for Whites. As a result, the rates for Whites in this study may have been overestimated (and the rate ratio underestimated) because Hispanic women have been identified as a high-risk group for cervical cancer.[9–11] Alternatively, if the number of non-Whites was underestimated, the comparisons between Whites and non-Whites may have exaggerated the race differential in mortality.

The >30% poverty group comprised a greater proportion of Hispanics to Whites than did the ≤30% poverty group.[12] The inclusion of Hispanic women in the White category may, in part, account for the insignificant race difference observed in the group with >30% poverty in contrast to the ≤30% poverty group, in whom race differences were significantly more marked. Two other explanations for this finding can also be given. First, the stresses associated with poverty may present barriers to obtaining preventive health services for both Blacks and Whites residing in the most economically disadvantaged communities.[13] Alternatively, whereas social class may be more similar between Whites and Blacks in the >30% poverty group, social class may be more disparate between Whites and Blacks in the ≤30% poverty group. Although our data can neither confirm nor reject these explanations, other studies have shown that race differences in Pap smear screening[14] and incidence of invasive cervical cancer[16] are more marked in higher than in lower socioeconomic areas.

Because poverty status was defined at the group level (according to the percentage of residents living below the national poverty level in the community where each study subject resided), no definitive conclusions may be applied on an individual basis. However, because community areas in Chicago tend to be particularly homogeneous with respect to socioeconomic status, significant misclassification was unlikely. Moreover, group-level definitions of economic status have

been used in other studies of race differences in cervical cancer, which reported results similar to those in studies that used individual indicators.[15,16]

Investigators have suggested for many decades that disparities in screening, in part, account for the excess cervical cancer mortality in Black women.[14,17–20] More recent data from the Behavioral Risk Factor Surveillance System, however, showed that a higher proportion of Blacks than Whites obtained Pap smears.[21] Results from the 1987 National Health Interview Survey demonstrated that poor White women were more likely to have never had a Pap smear than poor Black women.[22] These findings suggest that patient treatment and follow-up also play an important role in the excess mortality in cervical cancer seen in Blacks. Improved recording of Pap smears, specifically through efficient registries, has been recommended to provide better tracking of women with abnormal cytology reports and to promote provider adherence to screening and treatment guidelines.[23,24]

In addition to disparities in screening practices, the race differential in cervical cancer mortality can also be viewed as a function of the less favorable survival experience seen among Blacks. Black women are not only less likely to be diagnosed with localized cervical lesions, but are less likely than Whites to survive at the same stage of diagnosis.[18,25]

In summary, our findings are consistent with other studies reporting a nearly twofold race differential in cervical cancer mortality between White and Black women. The results from this study support intervention efforts focused on reducing cervical cancer mortality among Black women in Chicago. Future studies might attempt to improve measurement of social class to better assess its role in cervical cancer mortality. □

Access to Family Planning Services and Health Insurance among Low-Income Women in Arizona

Bradford Kirkman-Liff, DrPH, and Jennie Jacobs Kronenfeld, PhD

ABSTRACT

This paper uses 1984 and 1989 Arizona survey data to explore the importance of insurance coverage for access to family planning services. In Arizona, Medicaid was provided through the Arizona Health Care Cost Containment System, a managed care model. Family planning was not provided in 1984 but had been added by 1989. Low-income women were 2.3 times more likely to receive services in 1989 than in 1984. Women in the system were 60% more likely to have received services. To improve access, health reform proposals should explicitly include family planning in managed care benefits packages. (*Am J Public Health.* 1994;84:1010–1012)

Introduction

How important is insurance coverage, including Medicaid and employment-based insurance, in ensuring access to family planning services for low-income women? These questions are addressed through analysis of 1984 and 1989 Arizona telephone survey data. During the discussion of health care reform, these are especially important questions to answer.[1,2] Many reform proposals advocate development of a minimum, basic health benefits package; some exclude family planning as a covered service.[3,4] The fate of special family planning programs such as those funded under Title XX and Title X is unclear.[5]

Reform proposals include use of managed care (e.g., health maintenance organizations, preferred provider organizations) to contain costs. Medicaid is not excluded from reform: Medicaid recipients have a choice among competing plans rather than a separate Medicaid program.[6,7] These proposals generally assume that family planning services will continue to be covered by Medicaid, but as part of a package of services through managed care.[8,9] One concern is that preventive services, such as family planning, might be underprovided to Medicaid women less skilled in seeking care under managed care systems.

This paper uses Arizona survey data from 1984 and 1989 to examine the use of family planning services among low-income women in the state's managed care Medicaid program (the Arizona Health Care Cost Containment System). Of special interest is the impact of a change of policy in this program.

Until 1981, Arizona had no Medicaid program. A managed care/health maintenance organization alternative to traditional fee-for-service Medicaid—the Arizona Health Care Cost Containment System—was begun in 1982. The program operates through a network of capitated, managed care plans with primary care physicians as gatekeepers who coordinate all services. Plans competitively bid, negotiate for contracts, and are at financial risk for overuse. Eligible recipients must obtain all care from their selected plan.[10,11] When the program was implemented, waivers excluding family planning services were granted. This waiver was eliminated in 1986, and program contractors had to either provide family planning services or pay for referrals. Most types of family planning were included (oral contraceptives, intrauterine devices, sterilization, and implants). Using survey data from 1984 (when family planning was a waived benefit) and 1989 (when family planning was covered), we examined the impact of this policy change. Because the surveys included women who were uninsured and who had employment-based insurance, we can also compare access across forms of insurance.

Methods

Survey data were collected in 1984 and 1989 as part of a larger study investigating health status and barriers to health care. Both surveys were conducted by Louis Harris and Associates Inc and commissioned by the Flinn Foundation. The 1984 survey consisted of 2508 interviews with low-income adults. The 1989 survey consisted of 3104 interviews with adults of all income levels (1847 of low income). Low income was defined as 200% of the eligibility level of the state's medically indigent component of Medicaid in that year. Rural areas were oversampled in both surveys. Samples were weighted to the latest Bureau of the Census population parameters on region, education, sex, race, and age. Further details on this survey have been published

The authors are with the School of Health Administration and Policy, College of Business, Arizona State University, Tempe.

elsewhere.[12] For these analyses, a subsample of low-income respondents was drawn from the 1989 survey that matched the low-income definition used in 1984, adjusted for inflation.

In addition to insurance status and the Arizona Health Care Cost Containment System, other variables were hypothesized to affect use of family planning services.[13,14] Different cultural values of Latino women may lead to different use patterns.[15] (Numbers were too small to allow analyses of African-American and Native American women.) Higher levels of educational attainment would affect receptivity to family planning messages, increasing use. Women living in rural Arizona would have lower rates of use of family planning services, given less access to clinics and greater hostility toward services.[16] Age would have a strong effect, with highest use among younger women. Employed women are more likely to use family planning services.

Univariate analysis examines percentage differences and changes over time. A more rigorous approach involves the use of logistical regression to model the dichotomous measure, simultaneously considering all independent variables. The results were transformed into odds ratios and 95% confidence intervals; odds ratios that did not include 1.0 in the confidence range can be considered statistically significant at a 95% confidence level. Analyses were conducted for the entire sample and repeated for women 18 to 29 years old.

Results

Univariate Analysis

Table 1 presents the percentage of low-income Arizona women who received family planning services in 1984 and 1989 and chi-square tests for the difference between 1984 and 1989. There was a significant increase in use of family planning services over these 5 years, from 17.2% in 1984 to 33.2% in 1989. This increase was most striking among women 18 to 20 years old; their use jumped from 18.6% in 1984 to 40.8% in 1989, with no increase for women between 30 and 39 years of age.

The shift between 1984 and 1989 varied with insurance status. Only 12.6% of low-income women with employment-based insurance had received family planning services in 1984; this significantly increased to 37.4% in 1989. Although the trends for women in Arizona's version of Medicaid and uninsured women were also in the same direction, differences were not significantly different.

Use by Anglo women did not change between 1984 and 1989, but Latino women's use significantly increased, from 13% to 34.4%. Less educated women's use also increased. There was no change for women living in rural areas; the difference for urban women was mostly due to the increase for women in the metropolitan Phoenix area.

Multivariate Analysis

As seen in Table 2, low-income women in Arizona were 2.3 times more likely to receive family planning services in 1989 than in 1984. Women between 18 and 29 years of age were also 2.3 times more likely to receive family planning services than women 30 to 39 years old. A more detailed estimation of age effects shows that women 21 to 24 years old were 4 times more likely than women 35 to 39 years old to receive family planning services. Overall, insured women were not more likely to receive family planning services when all other independent measures were considered. Women in the Arizona Health Care Cost Containment System were 60% more likely than uninsured women to receive services, with no difference for low-income women with employment-based insurance. After the multivariate approach had been used, Latino women were only 60% as likely as Anglo women to have used family plan-

ning services, despite the large increase in the percentage of Latino women using family planning services between the 2 years. There was no significant relationship between household employment status, education, or residence and family planning use when all other measures were considered.

Results for women 18 to 29 years old indicated that low-income women in this age group in Arizona were 2.4 times more likely to receive family planning services in 1989 than in 1984. Overall, the model for younger women and the model for all women are very similar.

Discussion and Conclusions

The results found in this study are surprising. We expected low-income women who were insured to have greater use of family planning services than women without insurance, yet this was not the case. Only when insurance status was separated into those with Medicaid and those with employment-based insurance was there improved access to family planning services, but only for the Medicaid-covered population. One probable explanation is that most employment-based insurance does not cover family planning services, while Medicaid does. There was a significant increase in use of family planning services by low-income women between 1984 and 1989, indicating that the inclusion of family planning services by the Arizona Health Care Cost Containment System had an impact. Even in 1984, women covered by the program had higher rates of use, although the service was not covered. There are three possible explanations. First, the capitated provider networks may have provided family planning services out of their retained earnings, as allowed by program regulation. Second, plans may have provided referrals to family planning clinics operated by county public health departments, community health centers, or nonprofit organizations that filled the gap caused by exclusion of family planning under Arizona's version of Medicaid. Third, women in the program could use their limited dollars to pay for family planning services because they did not have to pay for other health care services.

These results have important implications for health reform proposals. Family planning must be explicitly included in any managed care basic benefits package created as part of health reform. Medicaid—including a managed care model—must also continue to include family planning. Although public and private nonprofit agencies can contribute to ensuring access to family planning services, access is improved when family planning is a covered service. □

Sex Bias in the Management of Coronary Artery Disease in Quebec

William D'Hoore, PhD, Claude Sicotte, PhD, and Charles Tilquin, PhD

ABSTRACT

This study tests the hypothesis that, given the absence of financial barriers to major coronary procedures in Quebec, women are as likely as men to undergo such procedures. The use of coronary procedures in 33 940 patients with ischemic heart disease, admitted during 1 year to 78 Quebec hospitals, was analyzed. The male-to-female age- and severity-adjusted odds ratios for the use of these procedures were 1.47 for diagnostic procedures, 1.38 for therapeutic procedures, and 1.26 for diagnostic and therapeutic procedures. These results suggest that differences in the use of coronary procedures by sex are influenced by factors other than financial accessibility. (*Am J Public Health.* 1994;84:1013–1015)

Introduction

Recent studies have shown that in the United States, women with coronary artery disease are less likely than men to undergo major diagnostic and therapeutic procedures.[1,2] This puzzling finding prompted us to examine the use of coronary procedures in Quebec hospitals to assess the magnitude of a possible sex bias. As elsewhere in Canada, there is free access to care in Quebec; therefore, there is no financial barrier as there could be in the United States. Given the absence of financial barriers, our hypothesis was that women are as likely as men to undergo major coronary procedures, after adjustment for severity.

Methods

To test this hypothesis, we used the MED-ECHO hospital discharge abstract database (Quebec, Canada). The analysis included all 33 940 patients with ischemic heart disease (*International Classification of Diseases*, ninth revision[3] [ICD-9] codes 410, 411, 413, 414) admitted during the administrative year 1989/90 to the 78 Quebec hospitals with 100 or more acute-care beds. A distinction was drawn between diagnostic procedures (coronary angiography and cardiac catheterization) and therapeutic procedures used for revascularization (percutaneous transluminal coronary angioplasty and coronary artery bypass graft). Logistic regression analyses were performed to relate the use of coronary procedures to predictors including sex, age (<50, 51–60, 61–70, 71–80, and >80 years), diagnosis (myocardial infarction vs other ischemic heart disease), and the Charlson index of comorbidity.[4] The Charlson comorbidity index ranges from 0 to 24, a higher score indicating a heavier burden of comorbid disease.

Results

Summary statistics are presented in Table 1. Of the 33 940 patients, 66.32% were male. The women were older than the men and scored higher on the comorbidity index. A total of 7935 patients (23.4%) had coronary angiography or cardiac catheterization, and 5983 patients (17.6%) underwent percutaneous transluminal coronary angioplasty or coronary artery bypass graft. Both diagnostic and therapeutic procedures were performed at the same time in 1850 patients (5.5%). Age and comorbidity were inversely associated with the presence of either diagnostic or therapeutic procedures. The presence of myocardial infarction strongly reduced the likelihood of diagnostic and therapeutic procedures.

Tables 2 and 3 show, respectively, crude and case mix–adjusted relative risks for the use of coronary procedures. The bivariate and multivariate estimations are similar: women were less likely than men to be treated aggressively. However, once a diagnostic procedure was performed, there was no difference between men and women in the use of revascularization. Therefore, we tried to refine the analysis of the use of diagnostic procedures. Logistic models including interaction terms between sex and other variables and terms testing for nonlinearity in the logit of the dependent variable were evaluated. The interaction between age and comorbidity was found to be the only significant term. The effect of age appeared to be nonlinear: older patients were much less likely to undergo diagnostic procedures than were younger patients (for patients aged 61–70, 71–80, and >80 years in comparison with patients younger than 50 years, the relative odds were, respectively, 1, 0.60, and 0.11). In all models, the association between sex and the use of diagnostic procedures remained strongly significant.

Finally, we assessed the outcomes of care in relation to the use of coronary

Total sample	33 940	0.89	0.81, 0.97
With revascularization	5 983	0.81	0.55, 1.20
With no revascularization	27 957	0.89	0.81, 0.98

procedures (Table 4). The overall mortality of women was higher than the mortality of men, but this difference disappeared when only patients who underwent a therapeutic procedure were considered. On this subject, we must note that the accuracy of fit of logistic models, measured by the area under the receiver operating characteristic curve,[5,6] was higher for the prediction of death (about 0.86, a level as good as can be reached by models with clinical data[7]) than for the prediction of use of coronary procedures (0.67 or less).

Analyses performed separately on low-risk patients (age < 70 years and comorbidity index = 0) and high-risk patients (age > 70 years and comorbidity index > 1) led to the same results: women with coronary disease were less likely than men to undergo coronary procedures.

Discussion

The differences between men and women in the use of coronary procedures are striking. Our results show that physicians' decisions to perform diagnostic procedures vary nonlinearly according to the age of patients, as if an implicit cutoff were present. Patients' preferences may explain this result. For example, older patients with ischemic heart disease are possibly more often widowed or alone, a factor that may deter them from seeking aggressive care.[8,9] However, age does not completely account for the differences between the sexes. Physicians may believe that diagnostic procedures are more risky in women and that the subsequent benefit of performing revascularization is smaller for women than for men. Physicians' decisions seem to depend on the patient's sex instead of his or her clinical status. However, given the poor fit of logistic models that predict procedure use, the clinical context that allows physicians to appropriately prescribe coronary procedures may not be grasped by such variables as age and comorbidity.

With regard to the higher mortality of women, it seems that although it is less frequent, ischemic heart disease is more severe in women than in men. Women may be referred for coronary surgery at a more advanced stage of disease than are men.[10]

We do not know whether coronary procedures are underused in women and overused in men, because it was not possible to assess the appropriateness of these procedures. Therefore, physicians should readjust the management of coronary disease in both women, who may not be undergoing beneficial procedures, and men, who may be undergoing procedures that are not beneficial. However, we are inclined to favor the hypothesis that coronary procedures are underused in women, given women's higher mortality, which is interpreted here as a referral bias.

Since our results are nearly identical to what was found in the United States,[1,2] they suggest that sex differences in the use of coronary procedures are not influenced by factors such as health services organization or financial accessibility. □

Health Insurance Coverage among Persons with AIDS: Results from a Multistate Surveillance Project

Theresa Diaz, MD, MPH, Susan Y. Chu, PhD, Lisa Conti, DVM, Bernard L. Nahlen, MD, Bruce Whyte, MD, Eve Mokotoff, MPH, Anne Shields, MHA, Patricia J. Checko, MPH, Mary Herr, MT, Quaiser Mukhtar, PhD, Cornelis A. Rietmeijer, MD, MSPH, Anna Levy, MPH, Pat Hermann, MD, and James W. Buehler, MD

ABSTRACT

To determine factors associated with health insurance coverage among persons with acquired immunodeficiency syndrome (AIDS), we interviewed 1958 persons 18 years of age or older who were reported to have AIDS in 11 states and cities. Overall, 25% had no insurance, 55% had public insurance, and 20% had private insurance. Factors associated with lack of insurance varied by current employment status. Employed persons with an annual household income of less than $10 000 were 3.6 times more likely to lack insurance than employed persons with a higher income. Unemployed persons diagnosed with AIDS for less than 1 year were two times more likely to lack health insurance than unemployed persons diagnosed for a longer time. Making insurance available to persons identified as most likely to lack insurance should improve access to care for persons with AIDS. (*Am J Public Health.* 1994;84: 1015–1018)

Introduction

Access to and use of health care services are affected by insurance status.[1–5] Increasingly, coverage for acquired immunodeficiency syndrome (AIDS) cases is shifting to public insurers, such as Medicaid,[6] most likely resulting from loss of private insurance among persons with AIDS[7–9] and demographic shifts in populations affected by the human immunodeficiency virus (HIV) epidemic.[10,11] To describe insurance coverage among persons with AIDS, we used information from a multistate interview project.

Methods

Eleven state and local health departments are collaborating with the Centers for Disease Control and Prevention (CDC) in the Supplement to HIV/AIDS Surveillance project. This project expands information routinely collected via AIDS surveillance through personal interviews of persons with AIDS. Persons reported with AIDS who are 18 years of age or older and are medically able to complete

[b]Includes persons of Asian, Pacific Islander, American Indian, and Alaskan native race/ethnicity.
*$P < .05$, interviewed compared with not interviewed.

the interview are eligible, as previously described.[12] Six sites used a population-based sample in which interviews were attempted with all eligible persons (Arizona, Delaware, South Carolina, and New Mexico) or with a 30% random sample of men who have sex with men (Los Angeles and Washington) and all persons with other modes of transmission. Five sites (Denver, Detroit, Connecticut, Florida, and Georgia) used a facility-based sample in which interviews were attempted with all eligible persons at selected medical facilities. Because these facilities were mostly public hospitals or clinics, insurance coverage varied by sampling method. Each participating health department developed procedures to ensure patient confidentiality, and projects were approved by local human subjects review boards.

We analyzed data for persons reported to have AIDS from June 1, 1990, through June 30, 1992. Participants were asked whether they currently had health insurance (including public insurance) and, if so, what type of insurance they mainly used to pay for HIV-related health care. For purposes of analysis, private insurance included both self-paid insurance (including self-paid COBRA insurance) and employer-provided insurance; public insurance included Medicaid, Medicare, state-funded insurance continuation (including state-funded COBRA insurance), the Civilian Health and Medical Program of the Uniformed Services, and coverage by the Veterans Administration. (The Consolidated Omnibus Budget Reconciliation Act [COBRA] of 1985 allows individuals to continue private health insurance they received when employed for 18 to 29 months after loss of employment. States can pay health insurance premiums, with matching federal funds, for individuals who stopped working because of illness and can no longer afford premiums.) Income was defined as household income in the year preceding interview, before taxes.

In a multivariate analysis, logistic regression[13] was used to determine factors associated with no insurance. We included variables significantly associated with no insurance in the univariate analysis (time since AIDS diagnosis and sampling method), as well as two variables most likely to change over time (employment and income). Because factors associated with lack of insurance differed by employment status, odds ratios were calculated separately for unemployed and employed persons. When results differed by sampling method, odds ratios were calculated separately.

Results

Description of Respondents

Of the 2675 eligible persons with AIDS selected for interviews, 1958 (74%) completed interviews, 331 (12%) refused to be interviewed, and 386 (14%) could not be located. Compared with persons not interviewed, those who were interviewed were more likely to be female, to have a known exposure mode, and to be Black (Table 1). Characteristics of persons interviewed were comparable to those of persons with AIDS reported in the United States during the study interval except for a lower proportion of Hispanics (Table 1). The median age of respondents was 36 years (range = 18–77 years); 74% were 30–49 years of age.

Health Insurance Coverage

Overall, 25% of respondents had no insurance, 20% had private insurance, and 55% had public insurance (Table 2). Among those with private insurance, 71% had employer-provided insurance, and 29% had self-paid insurance. Among persons with public insurance, 90% had Medicaid, 4% had Medicare, 3% had state-funded assistance programs, 2% were part of the Civilian Health and Medical Program of the Uniformed Services or the Veterans Administration, and 1% had state-funded insurance continuation (including COBRA).

Eighty percent of persons with public insurance and 51% of persons with private insurance stated that their insurance paid for all treatments. Respondents with Medicaid had the highest proportion (83%) stating that all services were covered, and persons with Medicare had the lowest proportion (18%). Forty-eight percent of persons with private insurance and 74% of persons with Medicare said their insurance paid for some but not all treatments.

In the univariate analysis, characteristics significantly ($P < .05$) associated with not having insurance included being diagnosed with AIDS for less than 1 year and being selected from a facility-based sample (Table 2). In the multivariate analysis, among employed persons, having a household income of less than $10 000 in the past year (adjusted odds ratio [AOR] = 3.6, 95% confidence interval [CI] = 2.6, 5.1) was associated with lack of health insurance; no association was found with time since AIDS diagnosis. Among unemployed persons from the population-based sample, having an income of less than $10 000 (AOR = 1.7, CI = 1.2, 2.5) and being diagnosed with AIDS for less than 1 year (AOR = 2.2, CI = 1.4, 3.4) were associated with lack of health insurance. Conversely, among unemployed persons from facility-based samples, per-

sons with an income of less than $10 000 (AOR = 1.7, CI = 1.2, 2.0) were more likely to have insurance than persons with a higher income; being diagnosed with AIDS for less than 1 year continued to be associated with no insurance (AOR = 2.1, CI = 1.7, 2.6).

Discussion

Among persons with AIDS, eligibility for public insurance has increased and public resources are used extensively for health care.[5,6,14,15] Regardless of race/ethnicity, sex, or HIV exposure mode, we found the majority of our respondents relied on public insurance (mostly Medicaid) for medical care. Yet despite the increased eligibility for publicly funded insurance for persons with AIDS,[16,17] one quarter of our respondents still lacked health insurance, similar to the proportion of all persons in the United States age 18–44 years who lack health insurance (14%–27%).[18,19] A preliminary analysis of 821 persons with HIV infection but not AIDS who were interviewed as part of this project found that an even higher proportion (40%) reported no health insurance (CDC, unpublished data).

In the United States, income is an important predictor of lack of health insurance coverage, with 47% of those with incomes below the poverty level lacking health insurance in 1987.[19,20] We found this generalization to be true for all employed persons and for unemployed persons from the population-based sample. However, among the unemployed in the facility-based sample, persons with lower incomes were more likely to have insurance. This finding is not surprising because although overall the facility-based sample had a higher proportion of persons with no insurance (as would be expected in public medical facilities), persons attending these facilities are probably provided with assistance in acquiring public insurance, and unemployed persons with low incomes would likely qualify. Regardless of sampling method, unemployed persons who had been diagnosed with AIDS for less than 1 year were more likely to lack health insurance than unemployed persons who had been diagnosed for at least 1 year. This difference may reflect ineligibility for Medicaid because personal assets were too high or because of administrative delays in obtaining public insurance or time restrictions for Medicare eligibility.[15,20] For example, persons who were once employed and now receive Social Security Disability Income may have an income too high to qualify for Medicaid, but must wait 2 years before they have the option to buy Medicare.[16,17,21] Unless they receive funds under COBRA, such recently unemployed persons are unlikely to be able to continue the private health insurance they had when employed.[17,20]

Even among insured persons, inequities in health care may occur. We found differences in payments for medical treatment for HIV infection by insurance type, with Medicare recipients being the least likely to report that all services were covered by their insurance. The need to supplement insurance coverage with out-of-pocket funds may deter appropriate use of health care and result in adverse clinical outcomes.[3]

Improving the use of, and access to, health services for HIV-infected persons will require increased insurance coverage for both employed and unemployed persons. □

TABLE 2—Proportion of Persons within Each Group with Private, Public, or No Health Insurance

Characteristic	Sample Size	Insurance Type, %		
		Private	Public	None

The Reliability of Racial Classifications in Hospital Discharge Abstract Data

Jan Blustein, MD, PhD

ABSTRACT

Many studies demonstrating an association between race and the use of medical services have used hospital discharge abstract data. The quality of the measures of race in such data sources has heretofore been unexplored. Hospital discharge abstract data from New York State were used to identify 767 cardiac patients who had been admitted to a hospital twice. Racial classifications during the two admissions were concordant 93.7% of the time. Kappa was .89 for Blacks, .72 for Whites, and .43 for all other racial groups. Evidence suggests that the misclassification of race in hospital discharge abstract data is nondifferential; racial discrepancies in access to medical services are thus probably even greater than those previously reported. (*Am J Public Health.* 1994;84: 1018–1021)

Introduction

Numerous studies have shown that Black Americans receive fewer medical services than their White counterparts.[1-8] Much of that research has been based on data abstracted from hospital medical records and reported to administrative agencies. However, there have been no published investigations of the reliability or validity of patient racial classifications in hospital discharge data sets. This is remarkable for two reasons. First, several studies have cast doubt on the reliability of the clinical information in those data sources, raising broader questions about the overall quality of the measures therein.[9-11] Second, critics have increasingly questioned the validity of the racial classifications in secondary data sources.[12]

This report of the reliability of racial classifications in a hospital discharge data source examines the concordance between assigned classifications during successive admissions for patients admitted twice. It describes the likely implications of misclassification for bias in previous reports of interracial differences in service use. Finally, it describes some difficulties that arise in validating measures of race.

Methods

Source of the Data

The data source for the study was the Statewide Planning and Research Cooperative System (SPARCS), a hospital discharge abstract database maintained by the New York State Department of Health. It includes demographic, clinical, and billing information and is based on reports from individual hospitals. For each patient who is discharged, hospitals cull information from various sources. For example, clinical information is ab-

stracted from patient medical records by trained record abstractors.

Interestingly, demographic classifications such as gender and race are not based on information abstracted from medical records. Rather, according to various knowledgeable sources, they are based on entries recorded by admitting clerks at the time that patients enter the hospital (oral communication, R. Davis, New York State Department of Health, September 1992; oral communication, B. Pavelcheck, Hospital Association of New York State, February 1994). According to those sources, race is generally assigned on the basis of encounters with patients or their proxies. There are no formal rules for assigning race to a patient. Because of the sensitive nature of racial identity, however, classification is often made by clerks' observations rather than by direct questioning.

Such procedures are apparently common in other states in which hospital discharge data are collected. For example, according to a document released by the California State Department of Health, racial classifications recorded by clerical staff at the time of admission are also generally the source of the race variable in that state's hospital discharge abstract system.[13] However, "classification of race/ethnicity is a difficult task. Hospital personnel [are] often unsure how to classify patients . . . [but are] reluctant to ask the patient directly."[13] In those cases, admitting clerks assign race as best they can.

In New York State, demographic, clinical, and billing data from each admission are merged to create the electronic database. For individuals admitted to a hospital more than once, records of those admissions can be linked by matching patient insurance billing numbers.[14] In this study, discharges were linked (i.e., ascribed to the same individual) if they had the identical billing number and reflected the same gender and date of birth.

Subjects

The 9576 subjects were part of a prior study of patients admitted to the hospital with a principal diagnosis of myocardial infarction in 1986.[15,16] During that index admission, there were substantial racial differences in cardiac service use (J. Blustein, unpublished data, June 1993). Specifically, patients classified as White were more than 60% more likely to receive a high-technology cardiac service (cardiac catheterization, angioplasty, or bypass surgery) than were patients classified as Black (odds ratio [OR] = 1.69, 95% confidence interval [CI] = 1.14, 2.50).

For various reasons, some of the patients were readmitted to a hospital during the subsequent 6-month period (hereinafter termed a "subsequent admission"). Subjects were selected for further analysis if they had been readmitted to a hospital other than the index hospital during a subsequent admission. Of the 9576 patients, 2487 were subsequently admitted; of those individuals, 767 were readmitted to a different hospital. None were admitted to three different hospitals.

Classification of Race

Race is classified as Asian, Black, American Indian/Eskimo/Aleut, "other," and White in the Statewide Planning and Research Cooperative System data set, consistent with federal guidelines.[17] A small number of patients are listed as "unknown." Because researchers using hospital discharge data have typically combined Asian, American Indian/Eskimo/Aleut, other, and unknown into the category "all other," the classifications Black, White, and all other were used for some portions of the analyses reported here.

Analytic Approach

Standard measures of crude concordance and kappa, the interrater reliability coefficient,[18] were used to calculate the extent of agreement between racial classifications during the index and subsequent admissions.

Results

In Table 1, racial classifications of the 767 subjects who were admitted to two different hospitals are compared with those of patients who were not admitted to two different hospitals. The two groups did not differ with respect to racial classification during the index admission ($\chi^2 = 6.2, 5\ df, P = .28$).

As shown in Table 2, racial classifications during the index and subsequent admissions were concordant in 719 of the 767 subjects (93.7%). The resultant percentage agreement and kappa for each racial classification are presented in Table 3. The reliability coefficients were .89 (95% CI = .82, .96) for Black race and .72 (95% CI = .64, .80) for White race. For other categories, reliability was even less consistent. When the other categories (other, Asian, American Indian, unknown) were combined, the interrater reliability coefficient was .43 (95% CI = .28, .58). Assessment of the reliability of the individual non-Black, non-White categories was limited by small sample sizes.

TABLE 1—Racial Classification of Patients during Their Index Admissions, by Whether They were Admitted to Two Different Hospitals (n = 9576)

	Admitted to Two Different Hospitals	
	Yes (n = 767), % (No.)	No (n = 8809), % (No.)
Black	6.4 (49)	6.3 (556)
White	89.0 (683)	88.6 (7806)
Other	3.9 (30)	4.1 (364)
Asian	0.3 (2)	0.5 (47)
American Indian	0.3 (2)	0.1 (5)
Unknown	0.1 (1)	0.4 (41)

Finally, as shown in Table 4, the use of cardiac services during the index admission was not associated with concordance between racial classifications during the index and subsequent admissions ($\chi^2 = 1.48, 1\ df, P = .22$).

Discussion

This study of hospital discharge abstract data revealed a substantial lack of reliability for racial classifications, particularly for non-Black, non-White categories. This pattern of results is consistent with previous reports comparing birth and death records[19] and with studies of discrepancies between self- and observer-classified race.[20]

As described above, the data analyzed here emanate from a study in which White cardiac patients were estimated to be 69% more likely than their Black counterparts to receive a high-technology cardiac service. The present findings suggest that this estimate of the effect of race may have been biased by measurement error. Is it possible to assess the extent of that bias? More generally, are estimates of the impact of race based on hospital discharge data sets likely to overstate or understate true racial disparities in access to services?

If misclassification of patient race is nondifferential (i.e., if the tendency to

TABLE 2—Racial Classification during Index and Subsequent Admissions for Patients Admitted to Two Different Hospitals (n = 767)

Classification during Index Admission	Classification during Subsequent Admission						
	Black	White	Other	Asian	American Indian	Unknown	Total
Black	41	5	3	0	0	0	49
White	0	665	17	1	0	0	683
Other	1	15	11	2	0	1	30
Asian	0	1	0	1	0	0	2
American Indian	0	1	0	0	1	0	2
Unknown	0	0	1	0	0	0	1
Total	42	687	32	4	1	1	767

TABLE 3—Percentage of Concordance and Interrater Reliability (Kappa) of Reported Racial Classifications during Index and Subsequent Admissions (n = 767)

Racial Classification	Concordance, %	Kappa	95% Confidence Interval
Black (n = 49)	99	.89	.82, .96
White (n = 683)	95	.72	.64, .80
All other (n = 35)	95	.43	.28, .58
Other (n = 30)	95	.32	.17, .47
Asian (n = 2)	99	.33	−.16, .82
American Indian (n = 2)	99	.66	0.4, 1.00
Unknown (n = 1)	99	−.00	.00, .00

Note. Percentage of concordance refers to the proportion of the 767 cases in which the two successive classifications were concordant for the dichotomy in question. For example, in 99% of the cases, patients were concordantly classified according to the dichotomy Black/non-Black. "All other" is an aggregated classification, including patients classified as other, Asian, American Indian, and unknown (see text).

TABLE 4—Concordance in Racial Classification and Rate of Use of Cardiac Services for Patients Admitted to Two Different Hospitals (n = 767)

	Race Classified Concordantly	
	Yes (n=719), % (No.)	No (n=48), % (No.)
Received cardiac services	12.1 (87)	6.3 (3)
Did not receive cardiac services	87.9 (632)	93.8 (45)

misclassify a patient as White or Black is independent of the likelihood that that patient will receive services), then the estimated racial discrepancy will be biased toward the null value.[21] Real discrepancies in service use will be greater than those reported.

There are several reasons to believe that misclassification of patient race is non-differential with respect to service use. First, racial classifications are assigned by hospital clerks at the time of admission, and, in most cases, decisions about providing services are made after admission. In those cases, misclassification is necessarily nondifferential. It is noteworthy that patients admitted emergently—including most patients admitted with myocardial infarction—will meet this description. In other cases, patients are electively admitted in order to receive services. Although those patients (or their proxies) may announce the intended treatment to the admitting clerk, it seems rather unlikely that clerks would classify patient race on that basis. Finally, the results reported in Table 4 are consistent with misclassification being nondifferential.

Recently, several investigators have used validation studies to "correct" effect estimates based on risk factors measured with known error.[22-24] However, it is not clear how these methods could be useful in correcting reported effects of race. Determining the sensitivity and specificity of racial classifications would require that there be some "gold standard" for race. As has been emphasized by many commentators, however, no such standard exists. Race is not a biological construct; rather, racial classifications are "based on socially defined phenotypic traits as seen through the filter of individual and social perspective."[25]

In explaining racial differences in cardiac service use, commentators have proposed two competing theories. One theory is that White patients may "prefer" more services than do Black patients.[1,2,4,8] The other is that physicians' treatment decisions are influenced—either consciously or unconsciously—by patient race.[1,2,4,8] These competing theories suggest two different validation sources. If the first theory is correct, then patients' self-categorization of race would probably be the logical gold standard. On the other hand, if the second theory is true, then physicians' perceptions of patients' race would be more appropriate.

In spring 1993, the working group from a conference convened by the Centers for Disease Control and Prevention recommended that, in all public health surveillance data sources, "race and ethnicity status should be self-identified using a multiple-choice option."[12] Implementation of this recommendation might well enhance the uniformity of the data collected by various agencies. However, if the second of the above-cited theories is true, access to services may depend less on self-categorized race than on the racial classifications and perceptions of others.

In conclusion, categorization of race in hospital discharge data exhibits a pattern of measurement error similar to that previously reported in other data sources used for public health surveillance. This misclassification is probably nondifferential; thus prior reports of the impact of race on service use are probably biased downward. However, because race is subjectively determined, it is not clear how to correct these misestimates of the impact of race on the use of medical services. □

The *American Journal of Public Health* (*AJPH*), published monthly, is the official Journal of the American Public Health Association, Inc, 1015 15th St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $13 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005. *AJPH* allotted $40; *The Nation's Health* allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters. Printed in the United States.

Advertising Sales: Maureen Sheridan, Advertising Manager, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on the first page of published article. For cost information on 100 or more reprints, contact Marilyn Butler, *AJPH* Reprints, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the Journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

Building Bridges between Schools of Public Health and Public Health Practice

Arden Handler, DrPH, Laura A. Schieve, MS, Pamela Ippoliti, MAT, Audrey K. Gordon, PhD, and Bernard J. Turnock, MD, MPH

ABSTRACT

A 1988 Institute of Medicine report, *The Future of Public Health*, characterized the current public health system as fragmented, particularly with regard to relationships between public health agencies and academic institutions. As one response to the report, the Health Resources and Services Administration established the Center for the Development of Public Health Practice at the University of Illinois to advance linkages between schools of public health and public health agencies. Surveys of schools of public health and of state health agencies were conducted in 1992 to collect baseline data on the practice links between the two. Responses reveal that there is a substantial amount of informal collaboration between them. Formalization of collaborative activities between schools and agencies is beginning to occur and is expected to expand owing to increased focus on public health practice at schools of public health. (*Am J Public Health.* 1994;84:1077–1080)

Introduction

The Institute of Medicine's 1988 report, *The Future of Public Health*,[1] cited many inadequacies in the current public health system and called for more formal interaction between public health academe and public health practice as one resolution to the problem. In response to the challenges of this report, the demands posed by the objectives delineated in *Healthy People 2000*,[2] and the recommendations of the Public Health Faculty/Agency Forum,[3] the University of Illinois at Chicago School of Public Health received funding in 1991 from the Health Resources and Services Administration to create the Center for the Development of Public Health Practice. The Center encourages and supports affiliation between schools of public health and public health agencies.

To provide a baseline portrait of collaboration between these two entities, two surveys were conducted in the winter of 1992, one distributed to schools of public health (school survey) and one distributed to state health agencies (agency survey). This report presents the results of these surveys in an effort to quantify the extent of practice activity at schools of public health since the publication of the Public Health Faculty/Agency Forum report.[3]

In developing the school survey, the recommendations of the Public Health Faculty/Agency Forum[3] guided the identification of the following core sentinel public health practice activities:

1. Public health practice steering/advisory committees
2. Multicomponent written agreements between schools of public health and public health agencies (i.e., contractual agreements or memoranda of understanding that are schoolwide and include two or more practice activities)
3. Faculty practice interactions such as faculty appointments at agencies, agency staff appointments at schools, and temporary faculty/agency exchanges
4. The development of clinical tracks at schools of public health
5. Formal practica relationships, including the joint development and evaluation of practica, the training of agency preceptors for their supervisory role, and the provision of funding for the student's participation in practica
6. Technical assistance from schools to agencies and vice versa
7. Joint research

The school survey distinguished between governmental public health agencies and governmental public health–related agencies. The former were defined as agencies that have as their primary purpose health promotion and disease prevention. These include local and state health departments and federal agencies such as the Centers for Disease Control and Prevention. Health-related agencies were defined as those agencies whose primary mission is *not* health promotion and disease prevention, although their functions relate to health. They include agencies such as departments of human services, mental health, and environmental protection. The results presented here focus mainly on governmental public health rather than on public health–related agencies.

The survey of state public health agencies included questions similar to those asked in the school survey. However, since many questions in the agency survey were aimed at obtaining qualitative information, most of the data presented here are from the school survey.

The school survey was sent to all 27 accredited schools of public health, located in 20 states and Puerto Rico. The

[a]Categories are not mutually exclusive.

agency survey was distributed to all state public health agencies in the 50 states, the District of Columbia, Puerto Rico, and the Virgin Islands. Telephone contacts were made with each school and agency to verify that they received the survey and to encourage participation. To increase the response rate, additional calls were then made to schools and agencies that did not reply by the deadline. Twenty-one schools, located in 16 states (77% response rate), and 37 health agencies (70% response rate) responded by the summer of 1992. Calls were made to all schools and agencies that returned surveys when responses needed clarification.

A moderate overlap was seen between responding states and schools; for 14 of the 21 responding schools (67%), the corresponding state health agency also responded. Additionally, state agencies were more likely to respond if a school of public health was located within their state, although this difference was not statistically significant (41% vs 23%, $P = .15$). Schools were not matched to their corresponding state health agencies for a comparative analysis, as it was found that many state agencies had linkages with schools located outside their boundaries and schools often engaged in activities with multiple state health agencies.

School Survey Results

All 21 responding schools reported participation in some practice activities with governmental public health and governmental public health–related agencies (Table 1). As expected, schools reported a higher level of interaction with the former agencies than with the latter ones. With both agency types, the most frequently cited activities were practica placements for students, technical assistance from the school for the agency, and faculty appointments for agency staff. What follows is an in-depth examination of specific sentinel public health practice activities taking place at schools of public health.

Public Health Practice Advisory Committees

Sixty-seven percent of the responding schools reported that they use some mechanism for organizing practice activities: 14% use an officially designated Public Health Practice Steering or Advisory Committee exclusively; 29% use another entity (usually a preexisting committee established for another function); and 24% use some combination of these two.

In 50% of the schools that use a formal entity to guide their practice activities (n = 14), at the time of the survey such committees had been in existence for less than 1 year; importantly, the timing of the inception or involvement of these committees in public health practice activities suggests that the Public Health Faculty/Agency Forum's recommendations have had a positive effect on many schools. However, in most schools, meetings of this advisory body occur less often than once a month; in only 29% does it meet monthly.

Formal (Including Multicomponent) Agreements between Schools and Agencies

Nearly all schools (n = 20) reported participation in practice activities with governmental public health agencies *without* formal written agreements, although many schools have several different arrangements with these agencies that include both formal and informal associations. When looking specifically at type of practice activity (Table 2), it is apparent that most interchanges between schools and governmental public health agencies take place without formal written agreements.

Only five schools at the time of the survey were using schoolwide multicomponent agreements. All five include in those agreements faculty appointments for agency staff and technical assistance from the school to the agency and vice versa (Table 2).

Among the 17 schools using either single-component, multicomponent, or both types of formal written agreements to guide their activities with governmental public health agencies, 15 have agreements with state health agencies, 15 have agreements with local health agencies, and 10 have agreements with federal agencies (Table 3). As expected, the most common collaborative activity is practica placements, but the large amount of technical assistance from schools to agencies at all levels indicates that this is also an important area of collaboration.

TABLE 3—Practice Activities Covered by Schools' Formal Written Agreements,[a] by Level of Governmental Public Health Agency

Practice Activity	Federal (n = 10)	State (n = 15)	Local (n = 15)
Practica	9	10	12
Joint research	6	8	5
Faculty appointments	5	7	6
Agency appointments	3	4	2
Temporary agency placements	4	2	2
Temporary faculty placements	4	2	2
Technical assistance from school	5	9	8
Technical assistance from agency	4	5	4

[a]Includes both multi- and single-component agreements (n = 17).

Strategies for Recruiting Public Health Agency Staff

The most common strategy used to promote the appointment of experienced public health practitioners to faculty positions is the adjunct appointment (n = 20). Joint appointments (not specified as clinical or academic) with a governmental public health or health–related agency are reported to be used by almost half the schools (n = 10). Full-time appointments using regular academic titles (n = 7) or clinical titles (n = 9) are each used by fewer than half the schools.

As a possible measure of more extensive commitment or involvement in public health practice activities, we examined the use of different appointment types by whether the school uses broad, multicomponent agreements. All schools that have such agreements also use clinical titles to bring practitioners into academe. Although nearly all schools *without* multicomponent agreements use adjunct appointments, only 25% of these schools use clinical appointments.

Practica

Only 57% of the schools (n = 12) reported that practica are required of all master of public health or equivalent (defined by each school) students; however, this is possibly an undercount as individual department requirements were not considered. The range of students participating in practica at each school is large (13 to 480 annually); approximately one third of these practica experiences involve governmental public health agencies. Encouragingly, 52% of responding schools have established a formal system of practica with governmental public health agencies, 71% indicated that a practica coordinator has been identified within the school, and 48% indicated that a practica coordinator has been identified within governmental public health agencies. Additionally, nearly all schools (n = 19) reported both joint development and joint evaluation of practica.

At the time of the survey, the majority of schools were not providing financial support for practica; however, most schools prepare preceptors for their supervisory role at least some of the time.

State Health Agency Results

Twenty-seven of the 37 responding state health agencies (73%) report participating in practice activities with an accredited school of public health. In agreement with the school survey, practica placements and the receipt of technical assistance from schools were the most frequently cited cooperative activities.

State health agency respondents were also asked if the temporary appointment of faculty from schools of public health to health department positions would be beneficial and, if yes (n = 35: 29 definitively and 6 unsure), to list the divisions where these appointments would be most helpful. The most frequently cited agency divisions for school-to-agency exchanges were environmental health, epidemiology, statistics, maternal and child health, and health planning and policy.

Comment

Together, the data from these surveys render a baseline picture of public health practice activities occurring at schools of public health; these results can be considered representative, given that the response rate to each survey was at least 70%. Whether public health practice activities are conducted informally by individuals or formally through project-specific agreements or through broad, schoolwide, multicomponent agreements may suggest whether these types of activities are supported at the highest levels at both the schools and the agencies. While informal linkages may be fruitful and productive, formal linkages and, in particular, the use of multicomponent agreements may indicate that the practice-academe relationship has been institutionalized. The responses here reveal a substantial amount of collaboration between schools of public health and public health and public health–related agencies; however, much of the collaborative activity reported at the time of these surveys had not been formalized and was occurring between individuals and units rather than between institutions.

Although these results overall suggest a considerable amount of interaction between schools and agencies, it is likely that collaborative activities between these institutions have actually been underestimated. Because there were a significant number of ambiguous answers in individual survey responses, we followed up all school surveys with a telephone call to clarify areas that were identified as being particularly problematic. These callbacks revealed that often the person completing the survey at a given school had difficulty replying for the entire school, given that practice activities were conducted on a departmental basis. Thus, a certain amount of collaboration probably went unrecorded.

With an increase in public health practice activity expected to have taken place at many schools of public health during 1992 to 1993, partly owing to what appears to be a concerted effort by schools to address the Forum's recommendations and partly owing to a public health practice grants initiative of the Center for the Development of Public Health Practice, it is anticipated that there will be a substantial expansion in

formal collaborative activities between schools of public health and public health agencies. Ultimately, it is expected that, as formal interaction between these entities increases and as additional resources are committed to this kind of activity, the training of the public health work force will be more fully integrated with the practice of public health. The goal is a more effective and more practice-based public health work force that will emerge better able to tackle the public health problems that face us all. □

Acknowledgments

This work was sponsored by the US Department of Health and Human Services, Health Resources and Services Administration, through a Public Health Service Special Project Cooperative Agreement (STC-D 1 D38 AH00046-01) with the University of Illinois at Chicago, School of Public Health, Center for Public Health Practice.

This material was previously presented at the 120th Annual Meeting of the American Public Health Association; October 1992; Washington, DC.

We thank the schools of public health and the state health agencies that participated in and completed these surveys for their time and effort. Additionally, their comments and observations were invaluable in providing insight into the development of subsequent surveys and in helping us more clearly focus our efforts toward fostering relationships between public health agencies and academe.

The Effect of Ordinances Requiring Smoke-Free Restaurants on Restaurant Sales

Stanton A. Glantz, PhD, and Lisa R. A. Smith, BA

ABSTRACT

Objectives. The effect on restaurant revenues of local ordinances requiring smoke-free restaurants is an important consideration for restaurateurs themselves and the cities that depend on sales tax revenues to provide services.

Methods. Data were obtained from the California State Board of Equalization and Colorado State Department of Revenue on taxable restaurant sales from 1986 (1982 for Aspen) through 1993 for all 15 cities where ordinances were in force, as well as for 15 similar control communities without smoke-free ordinances during this period. These data were analyzed using multiple regression, including time and a dummy variable for whether an ordinance was in force. Total restaurant sales were analyzed as a fraction of total retail sales and restaurant sales in smoke-free cities vs the comparison cities similar in population, median income, and other factors.

Results. Ordinances had no significant effect on the fraction of total retail sales that went to restaurants or on the ratio of restaurant sales in communities with ordinances compared with those in the matched control communities.

Conclusions. Smoke-free restaurant ordinances do not adversely affect restaurant sales. (*Am J Public Health.* 1994;84:1081–1085)

Introduction

As the evidence that environmental tobacco smoke endangers nonsmokers[1–5] has accumulated, more and more communities have restricted or eliminated smoking in public places and workplaces. Several communities have enacted legislation that requires smoke-free restaurants, thereby protecting the public and, particularly, restaurant employees[6] from the toxic chemicals in secondhand tobacco smoke. Such legislation, however, is not in the interests of the tobacco industry because creation of smoke-free restaurants is a highly visible statement that tobacco use is no longer socially acceptable.[7] Thus, tobacco companies have sponsored front organizations like the Beverly Hills Restaurant Association, Restaurants for a Sensible Voluntary Policy on Smoking, Californians for Fair Business Policy, and the California Business and Restaurant Alliance to mobilize restaurants against local smoke-free ordinances.[8,9] This strategy achieved its first success in 1987, when the tobacco industry convinced the Beverly Hills City Council to repeal the first 100% smoke-free restaurant ordinance in California on the basis of undocumented claims that business dropped 30% because of the ordinance.[8,9] Because similar predictions for other cities have been published nationally, voiced repeatedly through public testimony, and regularly printed in news reports, we tested the hypothesis that the passage of a smoke-free restaurant ordinance is accompanied by an immediate significant drop in restaurant sales.[10]

This study analyzes sales tax data for the first 15 US cities to enact smoke-free ordinances affecting restaurants. The California cities of Auburn, Bellflower (which repealed its ordinance in March 1992), Beverly Hills (which amended its ordinance 4 months after it went into force), El Cerrito, Lodi, Martinez, Palo Alto, Paradise, Roseville, Ross, Sacramento, and San Luis Obispo, and the Colorado cities of Aspen, Snowmass Village, and Telluride have had such 100% smoke-free restaurant ordinances in force long enough to assess their effects. We also examined sales tax data from 15 comparison cities similar to the smoke-free cities in population, income, smoking prevalence, and other factors.[11–13] An analysis of restaurant sales as a fraction of total retail sales, and of restaurant sales in cities with smoke-free restaurant ordinances compared with those in similar cities that do not have smoke-free ordinances, shows no significant effects on business.

Methods

Data on taxable restaurant sales and total retail sales were obtained from the California State Board of Equalization[14] and Colorado State Department of Revenue[15] from the first quarter of 1986 through the first or second quarter of 1993 (depending on data availability) for the 15 communities that had smoke-free restaurant ordinances in force. Included were cities whose ordinances were in force for at least four quarters during this period, plus Beverly Hills and Bellflower, Calif, whose ordinances were repealed. Data were also obtained for 15 comparison communities where no such smoke-free

[a]1990 US Census of Population and Housing.[11]
[b]"Some" refers to no more than 60% seating areas for nonsmokers.
[c]Tobacco Use in California (reported by county)[12] for California and Behavioral Risk Factor Surveillance Study for Colorado (statewide) 1991.[13]
[d]Number of months for which data were available for this study.

ordinance was in force or where no more than 60% seating availability for nonsmokers occurred as a part of an existing ordinance (Table 1). Sales data for Aspen and its comparison city were collected from the first quarter of 1982 because Aspen's ordinance was passed in 1985. Data were recorded for "Eating and Drinking Places" and "Total Retail Sales." Published data for restaurant sales and total retail sales in the city of Paradise for the second, third, and fourth quarters of 1990 and in the city of San Luis Obispo for the fourth quarter of 1990 and first quarter of 1991 were corrected as instructed by the Board of Equalization to account for late-reported data (written communications from Robert Rossi, June 15, 1992, and July 20, 1993).

To account for population growth, inflation, and changes in underlying economic conditions, the fraction (F) of total retail sales at restaurants was computed as follows:

$$F = \frac{\textit{Restaurant Sales}}{\textit{Total Retail Sales}}.$$

If an ordinance adversely affected restaurants, this fraction would be expected to drop when the ordinance was in force. Restaurant sales in cities with ordinances were also compared with sales in comparable cities without ordinances as follows:

$$C = \frac{\textit{Restaurant Sales in City with Ordinance}}{\textit{Restaurant Sales in City without Ordinance}}.$$

Again, if an ordinance adversely affected sales this ratio would be expected to drop.

Data were analyzed with linear regression[16]:

$$y = b_0 + b_t t + b_L L + b_w W,$$

where y is the dependent variable (F or C), t is time needed to represent the

underlying secular trend, and L is a dummy variable that indicates whether a smoke-free restaurant law is in force. The estimate of the coefficient b_t quantifies the annual rate of increase (or decrease) in the dependent variable, y, each year. The dummy variable L quantifies the presence of a smoke-free restaurant ordinance as follows:

$$L = \begin{cases} 0 & \textit{If No Ordinance} \\ 1/3 & \textit{If Ordinance in Force for 1 Month of Quarter} \\ 2/3 & \textit{If Ordinance in Force for 2 Months of Quarter} \\ 1 & \textit{If Ordinance in Force for Entire Quarter} \end{cases}$$

The coefficient b_L quantifies the magnitude of the effect of the ordinance on the dependent variable. Because all of the Colorado cities under study are ski centers, the restaurant business is much stronger during the winter tourist season. To allow for this effect, the dummy variable W was included for the Colorado cities, set to 1 for the first quarter (the winter tourist season) and 0 otherwise.

Not only were data analyzed for each city separately, but all the data on restaurant sales as a percentage of total retail sales for all 15 cities with ordinances for the entire year period were pooled in a single analysis, including 29 additional dummy variables, to allow for between-city differences in the mean values of the fraction of total retail sales going to restaurants.

The variance inflation factors for each variable were computed to assess multicollinearity, and the Durbin-Watson statistic was computed to test for autocorrelation among the residuals. The variance inflation factors were always well below 2, and the Durbin-Watson statistic never reached statistical significance. A change is considered statistically significant when $P < .05$.

Results

Table 2 summarizes the results for total restaurant sales as a fraction of all retail sales (F), and total restaurant sales in cities with ordinances compared with those in the matched comparison cities (C). The first column in the table is the mean value observed from 1986 (1982 for Aspen) to the second quarter of 1993 to provide a comparison with the magnitude of the change associated with the ordinance.

Smoke-free ordinances generally had no statistically significant effect on the fraction of retail sales that went to restaurants or on total restaurant sales in cities with ordinances compared with those in cities without smoke-free ordinances (Table 2 and Figure 1). There is marginal evidence that the fraction of total retail sales to restaurants increased in two cities (Bellflower, $P = .025$; Martinez, $P = .008$) and decreased in one city (Roseville, $P = .039$). In a comparison of restaurant sales in one city with an ordinance versus one city without an ordinance, sales increased in one city (Palo Alto, $P = .004$) and decreased in another (Paradise, $P = .049$). The lack of consistent response suggests that these results may simply reflect random variation, given the large number of P values that were computed. Analysis of all the data in pooled regressions did not detect significant changes in the percentage of retail sales or sales in cities with smoke-free ordinances compared with those in cities without ordinances.

TABLE 2—Effect of Smoke-Free Restaurant Ordinances on Total Restaurant Sales

City	Mean	Effect of Ordinance: Change, b_L	Effect of Ordinance: P	Model: R^2	Model: P

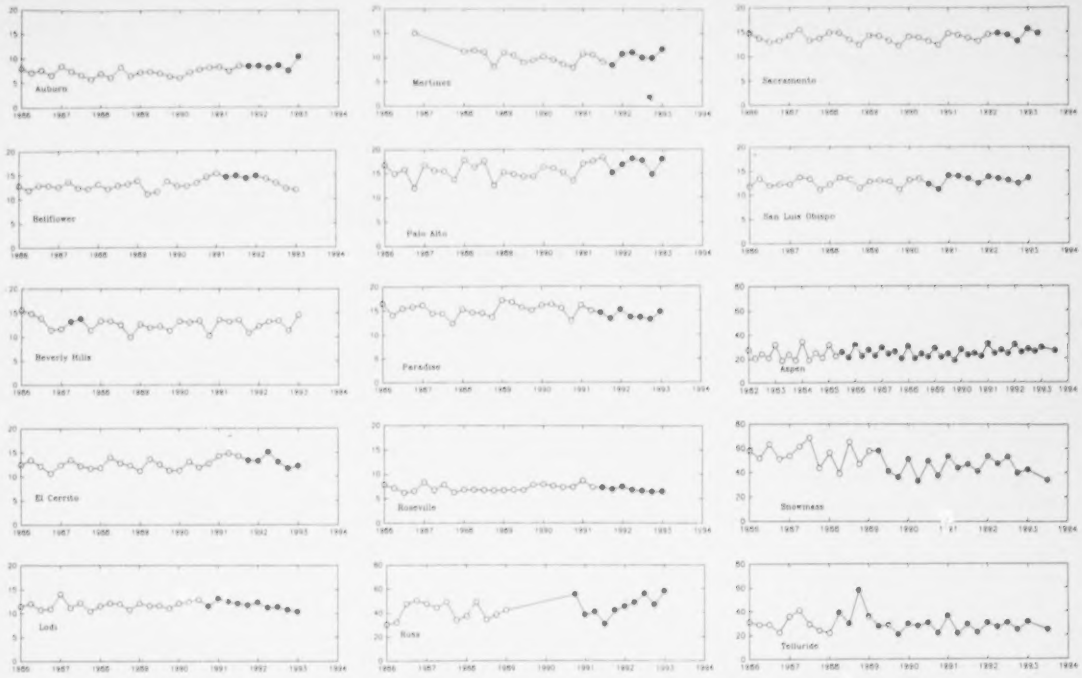
Beverly Hills is a particularly important case because it has been used by the tobacco industry to support the claim that smoke-free restaurant ordinances are associated with a 30% drop in business (Figure 2). However, data reveal that no such drop in sales occurred upon enactment, and that no increase in sales followed repeal 4 months later. Likewise, despite the fact that the Bellflower ordinance was repealed because of claims that business dropped, the ordinance was actually associated with a marginally significant ($P = .025$) increase in business.

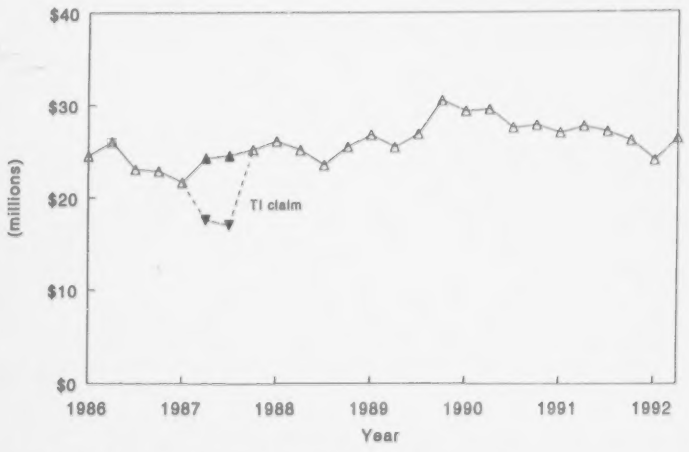
Discussion

This is the first comprehensive study that examines taxable sales data to determine the economic impact of smoke-free restaurant ordinances on restaurant sales. Using data from the California State Board of Equalization and the Colorado State Department of Revenue for pur-



Note. The quarters in which 100% smoke-free ordinances were in effect are represented by solid circles.

FIGURE 1—Restaurant sales as a percentage of total retail sales for the 15 communities included in the study.



Note. Period of smoke-free ordinance is indicated by the solid triangles.

FIGURE 2—The 100% smoke-free restaurant ordinance in force in Beverly Hills did not reduce sales by 30% (dashed line with "TI [tobacco industry] claim"), as the tobacco industry had suggested; rather, it had no significant effect on sales.

poses of paying sales taxes has several advantages. First, the numbers reflect *all* restaurant sales in a community, not just those of a small sample of restaurants. Second, the numbers are objective; they were collected through consistent methods by agencies with no interest in the effects of smoking restrictions on restaurant sales. Third, sales tax data can be expected to be reasonably accurate since it is a crime to lie in reporting the figures.

The communities studied in the report are different from each other and represent a cross-section of communities that might enact legislation controlling smoking in restaurants: Auburn is a small Sierra foothills community; Beverly Hills is a well-to-do urban city; Bellflower is a middle-class bedroom community; El Cerrito and Martinez lie within highly industrial areas; Lodi is a rural agricultural center; Palo Alto is a large suburban university community; Paradise is a small, semiagricultural community; Sacramento is a large city and the state capital; San Luis Obispo is a college town; Roseville represents a semirural bedroom commu-

nity; Ross is a small affluent San Francisco Bay community; and the three Colorado cities are mountainous, tourist resort areas. The fact that there were no adverse effects on business in these communities supports the conclusion that the results generalize broadly. Further, these 15 cities represent every city that has passed smoke-free ordinances that have been in effect long enough to study.

This study covers a significant period of time. It is important to take into account long-term (secular) trends as well as the quarter-by-quarter random variation and short-term economic changes. We avoided short-term analyses because it is generally possible to reach any conclusion desired by selectively picking the "correct" two quarters for analysis.[17] To avoid such biases and increase the power of the statistical analysis to detect an effect of the ordinances, we used data for a 7-year period (12 years for Aspen and Vail). This length of time allowed us to obtain good estimates of secular trends before evaluating any effects of the ordinances.

A common concern is raised about the possibility that patrons will dine in adjacent communities without such restrictions. Our data address this concern because the cities examined in this study are not isolated communities. Auburn, Lodi, Martinez, Paradise, Roseville, and San Luis Obispo, while not in large urban centers, are all surrounded by unincorporated areas that contain restaurants. Beverly Hills and Bellflower and their comparison cities, Santa Monica and Lakewood, are all located in Los Angeles County, a major metropolitan area in which all communities directly abut other communities. El Cerrito, Palo Alto, Ross, and their comparison cities all lie within the San Francisco Bay region. Sacramento and its comparison city, Fresno, both large urban centers, face competition from several neighboring communities. Although the skiing communities of Aspen, Telluride, and Snowmass Village are relatively secluded, other resort towns nearby that allow smoking would represent viable tourist alternatives to these smoke-free cities. If people were leaving these cities to dine in neighboring cities, our analysis would have detected it.

Another area of concern is the effect on bars since smoking and drinking are thought to go together. Revenues from bars and "full-service" restaurants are included in the sales tax data we used. The ordinances examined in this study contain different provisions governing bars independently and bars in relation to restaurants. Had there been a significant effect on sales in such restaurants, our analysis would have detected it. Furthermore, an analysis of individual classes of restaurants (based on whether they sell different types of alcohol) for four cities in California previously showed no effect when full-service restaurants were analyzed separately.[18]

Finally, the fact that the ordinances in Beverly Hills and Bellflower were repealed adds to the strength of our conclusions. Had the ordinances affected sales negatively, we would have expected to see an increase in sales following repeal. However, there was no increase in Beverly Hills, and sales dropped in Bellflower after the ordinance was repealed. Thus, legislators and government officials can enact such health and safety requirements to protect patrons and employees in restaurants from the toxins in secondhand tobacco smoke without the fear of adverse economic consequences. □

The Validity of Self-Reported Smoking: A Review and Meta-Analysis

ABSTRACT

Objectives. The purpose of this study was to identify circumstances in which biochemical assessments of smoking produce systematically higher or lower estimates of smoking than self-reports. A secondary aim was to evaluate different statistical approaches to analyzing variation in validity estimates.

Methods. Literature searches and personal inquiries identified 26 published reports containing 51 comparisons between self-reported behavior and biochemical measures. The sensitivity and specificity of self-reports of smoking were calculated for each study as measures of accuracy.

Results. Sensitivity ranged from 6% to 100% (mean = 87.5%), and specificity ranged from 33% to 100% (mean = 89.2%). Interviewer-administered questionnaires, observational studies, reports by adults, and biochemical validation with cotinine–plasma were associated with higher estimates of sensitivity and specificity.

Conclusions. Self-reports of smoking are accurate in most studies. To improve accuracy, biochemical assessment, preferably with cotinine–plasma, should be considered in intervention studies and student populations. (*Am J Public Health.* 1994;84:1086–1093)

Introduction

Smoking continues to be the largest single preventable cause of premature mortality and morbidity in the United States, yet 29% of American adults continue to smoke.[1] Efforts to promote cessation of smoking include interventions conducted with patients in clinical practices, in group environments such as schools and work sites, and in entire communities. Self-reports of smoking behavior are often assessed to determine the efficacy of these interventions. Observational studies and epidemiological studies of risk also incorporate measures of smoking behavior. Smoking is assessed in these studies to discriminate between smokers and nonsmokers, to measure change in smoking status, or to calculate pack-years of exposure retrospectively for risk assessment.

The validity of self-reported smoking is often questioned because of the widespread belief that smokers are inclined to underestimate the amount smoked[2,3] or to deny smoking at all.[4,5] As more attention is paid to smoking in the media and in public places, work sites, and clinical practice, individuals become sensitized to socially desirable forms of behavior. Thus, smokers may be more likely to exaggerate the extent to which their behavior conforms to the perceived social norm of "not smoking." Bias may be more common wherever social desirability is greater, such as in community-based studies in which intervention programs often seek explicitly to change community norms about the social acceptability of smoking.

Biochemical assessments of smoking by-products in body substances are often made to validate self-reports of smoking. Biochemical assessments can be viewed primarily as measures of the point prevalence of current smoking.[6] Because they are believed to be more objective and less susceptible to bias, biochemical measures are most often considered the "gold standard" in validation studies (i.e., they are considered more accurate than self-reports of smoking). Cotinine (in plasma, saliva, or urine), thiocyanate (in plasma or saliva), and carbon monoxide (in expired air) are the most commonly used biochemical assessments. Participants are either told in advance that such assessments will be made or asked for informed consent and specimens "on the spot." Sometimes the bogus pipeline procedure has been used, wherein subjects are informed that their self-reports can or will be objectively verified by the researchers by means of a biochemical test. In actuality, no verification takes place, although specimens are collected and left unanalyzed.[4]

Despite their believed objectivity, biochemical measures do not provide a gold standard, nor are they perfect measures of accuracy for use in assessing criterion validity. Carbon monoxide and thiocyanate can be elevated in those who do not use tobacco, and cotinine, although a specific metabolite of nicotine, can be elevated in users of snuff and chewing tobacco. When biochemical tests are

repeated, the results may be different even when smoking status has not changed. Biochemical measures also have practical drawbacks. Although nonreactive, these measures are obtrusive: blood, saliva, or breath samples need to be collected from the individual. Collection of samples involves more contact with respondents than usual in conducting large-scale field studies[3] and may result in increased refusals.[6] Because of the short half-life of smoking by-products in the body, biochemical assessment validates only smoking status near the time of specimen collection.[7] Costs can be considerable, ranging from less than $1 per sample for carbon monoxide to $20 per sample for cotinine analysis.[8] The cost of collecting, handling, and arranging for frozen storage of the specimens can add significantly to these estimates.

In contrast, self-reported smoking is assessed easily by using self-administered questionnaires in person or by mail or by using interviewer-administered questionnaires in person or on the phone. Questionnaires are noninvasive and inexpensive, and assurances of confidentiality of information can reduce refusals to participate. Self-reported information can be used to measure behavioral change, to calculate exposure risk, or to study pathways to smoking cessation or continuation.

The meta-analyses reported in this paper combine findings from a number of studies that validated self-reported smoking with biochemical measures, making it possible to examine the importance of different aspects of the studies, the populations, and the validation process. This paper addresses four major questions. First, what evidence exists to document the validity of self-reported measures of smoking behavior? Second, under what circumstances is it most important for investigators to consider biochemical assessment in studies of smoking behavior? Third, how do results change when using different statistical approaches for analyzing variation in the measures of accuracy and for pooling information across studies? Finally, how does this literature review inform the conduct of future validation studies, reports of smoking behavior, and the publication of results?

Methods

Description of Meta-Analysis Procedures

Meta-analyses are becoming common in both clinical and social science research.[9–11] Meta-analytic techniques were applied in this study to observations of the association between biochemical measures and self-reported smoking, similar to meta-analyses of diagnostic tests. Similar applications, such as the accuracy of the exercise electrocardiogram[12] and the human immunodeficiency virus antibody test,[13] have appeared in the literature. This application, like meta-analyses of randomized clinical trials, is an observational study of previously published studies.

Standard procedures were followed in accumulating and evaluating research studies for the meta-analysis.[9–11] We defined the problem as accuracy of self-reported smoking, with biochemical assessment as the criterion or concordance measure for evaluating validity. Bibliographic searches were conducted on all articles published between 1982 and 1991. Initially the MEDLINE database was used, with "smoking" as the subject head and the keywords "intervention studies," "evaluation," "community-based programs," and "education" as subheads. The Science Citation Index was used to trace articles referenced in studies previously identified in the bibliographic search. The Current Contents database was scanned for more recent articles through mid-1991, and references in these articles were also evaluated. Investigators familiar with smoking research at the Fred Hutchinson Cancer Research Center were also asked to identify appropriate studies from their literature files.

Thirty studies containing comparisons between self-reported smoking and biochemical assessments were identified. Studies confined to pregnant women were excluded. All studies were reviewed for information on the following characteristics: method of administration (self-administered vs interviewer administered), biochemical measures (cotinine, thiocyanate, or carbon monoxide), type of sample (air, blood, saliva), cutoff value used for biochemical definition of smoking, population (student vs general population), study design (intervention vs observational), sample size, ability to classify participants according to a 2 × 2 table based on self-report of smoking (yes/no) and the gold-standard definition of exceeding the defined cutoff level on the biochemical measure, and the smoking rate (i.e., prevalence of smoking), defined by the gold standard and self-report measures. The 2 × 2 table for calculating the accuracy of reports is shown in Figure 1.

		Respondent Exceeds Cut-Off on Biochemical Measure?	
		Yes	No
Self-Reported Smoking?	Yes	a	b
	No	c	d

FIGURE 1—The 2 × 2 table.

All the required data were available in 26 of the 30 articles identified as validity studies of self-reported smoking.[4,5,14–37] Four studies did not contain sufficient information to calculate accuracy measures, and these studies were eliminated from further analysis. Three members of the study team (Donald L. Patrick, Diane C. Thompson, and Susan Kinne) abstracted data independently to ensure quality control of the data used in the analyses. Discrepancies among the three abstractors were investigated and resolved after discussion. The 26 studies contained 32 comparisons based on independent samples and 51 comparisons wherein 2 or more comparisons were made on partial or total analyses of the same individuals. Table 1 contains the essential data abstracted from the studies included in the meta-analysis.

Measures of Accuracy

Data abstracted from the 26 studies were used to calculate two measures of self-report accuracy. For the purposes of this study, in which biochemical measures were considered the criterion measure, *sensitivity* was defined as $a/(a + c)$ in Figure 1, or the proportion of respondents with a positive level on the biochemical measure that reported smoking. *Specificity* was defined as $d/(b + d)$, or the proportion of respondents with a negative level on the biochemical measure that reported absence of smoking.

Analytic Models and Procedures

Cutoff levels were standardized into comparable units of measurement across studies for each type of biochemical measure and biological specimen. Studies using thiocyanate–saliva samples were eliminated from our analyses because of their outlying values for sensitivity and specificity after such standardization. We thus analyzed 47 of the 51 comparisons (allowing more than 1 comparison per

study) and 30 of the 32 strictly independent comparisons (allowing only 1 comparison per study, chosen at random).

Since there is uncertainty about how best to combine proportions across studies,[40] several analytic methods were used to obtain point estimates and confidence intervals of average sensitivity and specificity. The fixed-effects approach assumes that all studies are homogeneous and that the "true" sensitivity and specificity are the same for each study. Under this model, estimates from each study differ from this assumed true value only because of sampling variation, and the estimates from small studies tend to be worse than those from larger studies. In the fixed-effects model, the most efficient point estimate for sensitivity, for example, is the mean of the sensitivities weighted by sample size. This is equivalent to putting all of the people from all studies into one 2×2 table and estimating sensitivity and specificity from it. Confidence intervals are calculated from the weighted standard error. Regression analyses to determine correlates of accuracy can be achieved by using weighted ordinary least squares, with the study as the unit of analysis, or by using logistic regression. We used logistic regression to conduct fixed-effects analyses of the correlates of accuracy.

In actuality, however, studies are not homogeneous: they involve different study populations and different data collection methods. The "true" sensitivity and specificity values being estimated probably do vary among studies because of this heterogeneity. Under a random-effects model, variation among the studies is assumed to be due, in part, to the variation among the "true" values, as well as to sampling variation within each study. The correct weight in this case depends on both sources of variation. If the between-studies heterogeneity is large, this results in approximately equal weights for each study; if it is small, then the weights are approximately proportional to the sample size, as in the fixed-effects model. Laird and Mosteller[38] suggested a moment-based estimate for the mean, with its associated variance, that can be used to obtain confidence intervals for the random-effects method. This method computes appropriate weights for each study; these weights are a combination of the variance within studies and the variances among studies. If there is almost no variation among studies, then each study is weighted by its sample size. If there is great variance among studies, then each study will receive approximately equal weight. We computed the weights and found that the latter case was true for our data. The sensitivity and specificity estimates for our studies were so variable that the random-effects analysis essentially gave all studies equal weight. For this reason, to examine the effects of covariates under a random-effects assumption, we used simple ordinary least squares regression with the study as the (unweighted) unit of analysis and sensitivity and specificity as the dependent variables.

The sensitivity and specificity measures were negatively skewed. To test the sensitivity of the findings to this deviation from normality, we analyzed the logarithm of 100 minus sensitivity plus 1 and 100 minus specificity plus 1, which did have a reasonably normal distribution. The results of analyses using the logarithmically transformed measures were substantially the same as analyses with untransformed data; hence, for ease of interpretation, we report the original analyses.

We compared fixed-effects and random-effects models. For the purposes of this paper, we present unadjusted, bivariate results and multivariate analyses using the ordinary least squares random-effects regression (most conservative) and the fixed-effects logistic regression (least conservative). Independent variables in the regression analyses were method of administration (self-administered vs interviewer administered), study design (observational vs intervention), population type (student vs general population), and type of biochemical measure and specimen (cotinine–plasma as the reference vs cotinine–saliva, thiocyanate–plasma, or carbon monoxide [air and blood]). Two-way interactions among the study characteristics were examined in the random-effects ordinary least squares analyses of 47 comparisons; one interaction was entered at a time.

Results

A total of 36 830 respondents were included in the 26 studies and 51 comparisons. Of the comparisons reported in these studies, 37.7% were obtained from self-administered questionnaires and 62.3% were obtained by interviewers. Students represented 22.8% of respondents for the comparisons; 77.2% of respondents were drawn from the general population. Only 5.8% were respondents in intervention studies in which biochemical assessments were used. Carbon monoxide, thiocyanate, and cotinine were used as the biochemical measure in 54.8%, 18.2%, and 27% of the comparisons, respectively.

As shown in Table 1, sensitivity values ranged from 6 to 100 in the 51 comparisons; specificities ranged from 33 to 100. The average sensitivity for these studies, unweighted by sample size, was 87.5; the average specificity was 89.2. Tables 2 and 3 show results for sensitivity and specificity for all 47 comparisons and for the 30 strictly independent comparisons, respectively. For each sample, results are shown for the ordinary least squares random-effects and logistic fixed-effects models. The bivariate analyses show the effect on sensitivity or specificity of each study characteristic by itself. The multivariate analysis results come from regression models that included as predictors all of the study characteristics listed. Thus, they show the effect of each predictor on sensitivity or specificity after adjusting statistically for all of the other predictors.

For the fixed-effects analysis, the logistic regression coefficients were used to calculate the effect, in percentage points, of the study characteristic of interest when other characteristics (if any) in the model were held constant at their mean values. Effects for the ordinary least squares random-effects regression were the coefficients themselves. For example, per the random-effects ordinary least squares regression treating comparisons as independent (Table 2), interviewer-administered survey self-reports had a sensitivity that was 5.2 percentage points higher than that of self-administered survey reports, but this difference was not significantly different from zero ($P = .135$).

For sensitivity, the fixed-effects result for interviewer-administered studies was a 1.1 percentage point increase, which was significant at the .05 level. After controlling for all other study characteristics, the effect was a 4.0 percentage point increase in self-report sensitivity for the random-effects model (not significant) and a 1.2 percentage point increase in the fixed-effects analysis (marginally significant at $P = .066$). None of the study characteristics showed significantly different estimates for sensitivity in either the bivariate or multivariate random-effects analyses. For the fixed-effects approach, student populations and the type of sample were significantly related to sensitivity. Student populations yielded significantly lower sensitivity than general population studies. All biochemical samples yielded higher

sensitivity than cotinine–plasma, and interviewer-administered studies provided marginally greater sensitivity ($P = .047$).

For specificity, the random-effects model showed statistically significant lower estimates for thiocyanate–plasma, saliva cotinine, and carbon monoxide (both air and plasma) in comparison with plasma cotinine. When all study characteristics

were entered into the regression equation, significant beneficial effects for specificity remained only for cotinine–plasma in comparison with plasma thiocyanate samples.

Estimates of self-report accuracy using the fixed-effects analyses were much more likely to show statistically significant differences due to study and population characteristics than were the results of random-effects analyses. The ordinary least squares random-effects results in Table 2 (columns 2 and 4) illustrate the most conservative approach; the logistic fixed-effects results (columns 3 and 5) are less conservative under the assumption that studies are homogeneous. The ordinary least squares random-effects analyses, both bivariate and multivariate, showed no significant effects for sensitivity and significantly lower estimates of specificity for plasma thiocyanate samples using statistical significance as the criterion.

Table 3 shows the results of even more conservative analyses using only 30 independent comparisons, with 1 comparison chosen at random from each study eligible for analyses. Results were similar for sensitivity using the random-effects or the fixed-effects approach in both bivariate and multivariate analyses. No study characteristics produced significantly higher or lower estimates of self-report accuracy. Fixed-effects analyses of sensitivity were also similar for bivariate and multivariate analyses, indicating that all study characteristics produced the same higher or lower estimates. Results of studies with student populations yielded lower estimates of sensitivity. For specificity and the random effects analyses, significantly lower estimates were obtained for the different samples in comparison with plasma cotinine. All study characteristics were significantly different in the bivariate, fixed-effects analysis of specificity, except for observational studies (in comparison with intervention studies). This same pattern emerged with multivariate analyses of specificity using the fixed-effects approach, although the differences obtained from student populations no longer were evident.

An analysis of two-way interaction effects using the random-effects model and 47 comparisons yielded only one significant interaction each for sensitivity and specificity (interviewer-administered questionnaires in observational studies). Our power to detect interaction effects, however, was small given the small number of studies included in the analysis.

Discussion

This meta-analysis of published studies comparing self-reported smoking status with results of biochemical validation suggests generally high levels of sensitivity and specificity for self-report. Across all studies, the sensitivity of self-report was 87%, and the specificity was 89%. Nonetheless, both measures of accuracy proved quite variable among studies, as shown in Table 1, suggesting that specific aspects of the setting, study population, measurement methods, and study purpose are important to the accuracy of smoking self-reports.

Our search for systematic patterns of variation in sensitivity and specificity across studies was only partially successful. Two different methods of meta-analysis yielded generally similar results on the sign and magnitude of the effect of each study characteristic on sensitivity or specificity, but they often produced widely divergent verdicts on the statistical significance of those effects. The fact that the random-effects model produced *P* values that were usually much higher than those from the fixed-effects model indicates a large amount of between-study variability that could not be accounted for by the study characteristics measured. This conclusion, in turn, suggests that other unmeasured study characteristics may confound our results about the effects of method of administration, study population, study type, and biochemical test and specimen.

One of the most important unmeasured study characteristics is the specific wording of questions on smoking status. Very few studies reported this critical information, despite considerable evidence from survey research that responses are heavily influenced by how a question is phrased and the order in which questions are asked.

Because of these limitations, the observed patterns of association between accuracy of self-report and study characteristics must be interpreted with caution. The results suggest that interviewer-administered questionnaires yielded higher estimates of sensitivity and specificity than did self-administered questionnaires. Interviews identified more of the smokers correctly and classified nonsmokers more accurately. This may reflect smokers' awareness of sensory cues about their smoking (visible cigarettes, nicotine stains on teeth or hands, smoke odor) that would be obvious to an interviewer. More respondents may attempt to hide smoking behavior in self-administered questionnaires, even when biochemical validation is known.

Even in the most conservative analyses, student self-reports had lower sensitivity than studies using reports from subjects in the general population; however, the results were not always statistically significant. That is, students appear more likely to deny smoking, even when biochemical measures classify them as smokers. This is not surprising, since smoking by minors is illegal in most states and many young tobacco users have not yet defined themselves as smokers. Both of these conditions would contribute to a tendency, whether conscious (fear of being found out) or unconscious (self-definition inconsistent with behavior), to underreport. The different analyses do not suggest, however, that student self-reports have higher specificity than do those of subjects from the general population. Unfortunately, all studies of student populations reported here were observational in nature; no intervention studies with students that reported biochemical results were found among published studies, although the bogus pipeline procedures have been used with students. Reports of accuracy from intervention studies with student populations might have yielded lower estimates of sensitivity given the results from observational studies.

In the most conservative analyses, using only one comparison from each study and the random-effects approach, observational studies had higher levels of sensitivity than intervention studies, a conclusion supported by a qualitative review of studies in the 1990 surgeon general's report.[3] Self-reports from subjects in intervention studies, in which there is an expectation of cessation of smoking, are more likely to involve underreporting of actual smoking.

Self-reports of participants in intervention programs also have lower specificity, meaning that more biochemically validated nonsmokers reported smoking. Biochemical tests have limited ability to detect the very low levels of smoking that would be expected from recent quitters who "slip" and smoke an occasional cigarette.[34] Discussions of quitters' reactions to such slips (the abstinence violation effect) suggest that the would-be quitter is likely to exaggerate the importance of a few cigarettes under these conditions.[39] This can produce a report of "smoking," although its magnitude is smaller than the test can detect. In observational studies, with little focus on

cessation, this reaction may not be triggered.

Consistent with previous reports,[40] self-reports of smoking validated by means of cotinine–plasma biochemical measures appear to have higher specificity than those reports validated by other biochemical tests and specimens. The *P* values for tests comparing cotinine–plasma and other biochemical measures were not always significant in the more conservative random effects model, but the signs and magnitudes of the coefficients were mostly consistent across analytic models and between Tables 2 and 3. The observed pattern shows that more false-positive self-reports (i.e., respondents report that they are smokers when the biochemical test does not confirm such a report) tend to be observed in studies that use methods other than cotinine–plasma. This finding may reflect variation in the accuracy of the other biochemical tests in relation to self-reported smoking. These so-called false-positives may actually be smokers, but the poorer biochemical tests were too insensitive to detect relatively low levels of biochemical abnormality. There is no substantive reason to expect differences in self-report behavior due to the form of biochemical validation.

The fixed-effects and random-effects analyses yielded both different point estimates of the effects and different significance levels. Between-study variation was highly significant in all analyses, calling into question a key premise underlying the fixed-effects model. The results obtained from using multiple nonindependent comparisons in the different studies (Table 2) and from using only independent measures (Table 3) were substantially similar. Thus, the lack of independence in samples did not prove to be a serious problem for this meta-analysis.

In summary, our results suggest that biochemical validation may be more important in intervention studies, in studies with student populations, and in studies using self-administered rather than interviewer-administered questionnaires. For greatest accuracy, self-administered questionnaires given to students might benefit from biochemical validation, given the lower estimates obtained from these groups. Cotinine–plasma may be the biochemical test of choice if adequate resources are available for collection and analysis.

The decision to use biochemical validation is not as straightforward as it might appear. Biochemical validation is costly and sometimes difficult to obtain for all participants.[6] The bogus pipeline procedure and use of biochemical assessments with random subsamples of the target population are alternative strategies.[4]

The conclusions from this meta-analysis are subject to three major cautionary notes that, in turn, indicate needed improvements in the conduct and reporting of future studies of smoking behavior. First, it is known that the form and content of self-report questions about smoking influence the responses given and, hence, the categorization of respondents as smokers.[25] This observation argues that studies asking about smoking should report or reference the exact questions used so that this source of misclassification can be controlled. Second, authors of published studies need to make clear how biochemical validation was presented to study participants. In studies in which participants know that biochemical assessment will occurr, such as in the bogus pipeline procedure, self-reported smoking rates may be different from those in studies in which biochemical assessment is presented only at the point of collection. The exact procedures used in studies should be identified in the methods sections of articles to permit evaluation of the results according to the potential bias introduced by precollection announcement of biochemical validation.

Finally, in any meta-analysis, publication bias and the "file drawer phenomenon," the failure to submit for publication studies that do not produce effects, have an impact on the data available for analysis and can bias the outcome.[41,42] Although this bias is likely to be reduced in smoking studies that do not seek to test a specific hypothesis about validity, the universe of potential data sets on the validity of self-reports is still influenced by investigator analysis and submission of data for publication. This meta-analysis also excluded studies of pregnant women, and, thus, the generalizability of the results must be considered in comparison with the population under investigation.

The failure to include sufficient data on biochemical assessment resulted in the exclusion of several studies that reported validations of self-report. This suggests that in future studies with smoking validation, sufficient data should be published for investigators to confirm and evaluate the accuracy of self-reports. □

Estimating the Number of HIV-Infected Injection Drug Users in Bangkok: A Capture–Recapture Method

ABSTRACT

Objectives. The purpose of the study was to estimate the number of injection drug users infected with the human immunodeficiency virus (HIV) in Bangkok to allow planning for health services for this population.

Methods. A two-sample capture–recapture method was used. The first capture listed all persons on methadone treatment for opiate addiction from April 17 through May 17, 1991, at 18 facilities in Bangkok. The second capture involved urine testing of persons held at 72 Bangkok police stations from June 3 through September 30, 1991. Persons whose urine tests were positive for opiate metabolites or methadone were included on the second list.

Results. The first capture comprised 4064 persons and the recapture 1540 persons. There were 171 persons included on both lists, yielding an estimate of 36 600 opiate users in Bangkok. Existing data indicate that 89% of opiate users in Bangkok inject drugs and that about one third are infected with HIV, yielding an estimate of approximately 12 000 HIV-infected injection drug users in Bangkok in 1991.

Conclusions. During the 1990s the number of cases of acquired immunodeficiency syndrome (AIDS) and other HIV-related diseases, including tuberculosis, in the population of HIV-infected injection drug users in Bangkok will increase dramatically, placing new demands on existing health care facilities. The capture–recapture method may be useful in estimating difficult-to-count populations, including injection drug users. (*Am J Public Health.* 1994;84: 1094–1099)

Introduction

The explosive initial phase of the epidemic of human immunodeficiency virus type 1 (HIV-1) infection in Thailand occurred in 1988 among injection drug users in Bangkok, the capital, presumably as a result of transmission via the sharing of injection equipment.[1,2] The rate of HIV-1 seropositivity among opiate users seeking drug treatment in this city of 6 million people rose from 0% to 1% in late 1987 to 32% to 43% in late 1988.[2] From 1989 through 1993, seroprevalence among persons in opiate treatment programs stabilized at approximately 35% to 40%.[2] Existing data indicate that heroin is the principal drug used by 97% of persons seeking drug treatment in Bangkok and that 89% of such persons inject the drug.[3] Since 1988 the HIV-1 epidemic in Thailand has extended to persons with other risk behaviors for HIV infection; rates of HIV-1 seropositivity have increased dramatically among female prostitutes, young men seeking treatment at sexually transmitted disease clinics, and 21-year-old male military conscripts.[2,4]

An accurate estimate of the total number of injection drug users in Bangkok could be used to estimate the number of HIV-infected injection drug users. This estimate would be helpful in assessing the amount of HIV transmission that is due to injection drug use as compared with transmission due to sexual activity. Such an estimate could also be used to plan drug treatment programs and other health services for this population. In particular, an estimate of the number of HIV-infected injection drug users would allow for a reasonable prediction of the number of acquired immunodeficiency syndrome (AIDS) cases to expect among this population in the coming decade. The care of injection drug users with AIDS and HIV-related infections such as tuberculosis will likely place a great burden on existing health care facilities in Bangkok and elsewhere in Thailand.

We employed a capture–recapture method to estimate the number of opiate users in Bangkok and then used existing data to estimate the total number of injection drug users and the number of HIV-infected injection drug users in this city in 1991.

Background

Opiate use in Thailand dates back more than 300 years. Although there were

laws in the 18th century prohibiting the use of opium, the trade in and use of opium were regulated until 1959, when opium use was banned.[5] In 1959, opium smokers were required to register, resulting in the documentation of 70 985 users, about half of whom were in Bangkok.[5] Heroin use was not noted until shortly after 1959, and the practice of injecting heroin, predominantly by young men, increased in the second half of the 1960s.[5] Opium poppies have traditionally been grown in the mountainous Golden Triangle region that includes northern Thailand, Myanmar (Burma), and Laos. This region is one of the world's foremost heroin-producing areas. The street price (200–500 baht [US$8–20] per gram) of 60% to 90% pure ("No. 4 grade") heroin in Bangkok, 700 km to the south, is among the lowest in the world. Compared with the official daily minimum wage of 100 baht (US$4) in Bangkok, the relative cost of regular heroin use is considerably lower in Thailand than in other countries where illicit heroin use is a problem. A recent study in Bangkok indicated that 69% of 600 injection drug users had some form of legitimate employment, but also that 69% had spent time in prison since they began injecting heroin.[1]

Free treatment services for drug users in Bangkok are provided by the Bangkok Metropolitan Administration and the Ministry of Public Health. Law enforcement control is waived for clients.[6] The Bangkok Metropolitan Administration operates 17 outpatient drug treatment clinics throughout the city and the Ministry of Public Health operates Thanyarak Hospital, a 500-bed inpatient facility with an active outpatient department, in Pathum Thani on the northern edge of Bangkok. Methadone treatment, usually lasting 45 days, is the principal mode of opiate detoxification. Routine urine screening for opiates indicates that a large proportion (40%–80%) of persons receiving outpatient methadone treatment continue to use heroin while in treatment (Bangkok Metropolitan Administration, unpublished data). Admissions to treatment are reported to the Drug Dependence Information System, operated by the Office of the Narcotics Control Board of the Office of the Prime Minister and the Department of Medical Services, Ministry of Public Health, in collaboration with the Institute of Health Research, Chulalongkorn University.[6] In 1989, this system recorded 28 457 courses of drug treatment in Bangkok; 95% of the clients were men, 87% were aged 20 through 39 years, and 82% were outpatients.[3] Multiple treatments for the same person were recorded as separate events.

The total number of injection drug users in Bangkok is not reliably known; however, efforts have been made to estimate the number of persons served by the 17 Bangkok Metropolitan Administration treatment facilities. For the years 1986 through 1989, the number of treatment admissions ranged from 22 522 to 24 355. When duplicate names were eliminated from admission records, the number of persons treated annually ranged from 7238 to 8591, indicating an average of three treatment courses annually per patient served.[7,8] These data were used in a multiple-recapture analysis (using admission data from the three trimesters of a year as separate captures) to estimate the drug treatment population. In this analysis, the treatment population in the years 1986 through 1989 was estimated to be between 16 460 and 21 655 persons.[7,8] However, this method was thought to underestimate the total opiate-using population in Bangkok because it did not adequately account for persons not receiving treatment.

In 1989, the Bangkok Metropolitan Administration conducted a modified key informant study[9] of persons receiving methadone treatment to determine the proportion of heroin users in treatment. Clients were asked to list the persons they knew who used heroin and to indicate whether these persons had ever been admitted to a treatment program. The mean number of persons listed on 1944 questionnaires was 5.3 (SD = 3.2). The proportion of heroin users who had ever been in treatment was 0.626.[10] Dividing the estimated annual treatment population (16 460 to 21 655) by this proportion yields an estimate of 26 294 to 34 593 total heroin users. However, because this method assumes that all heroin users are known by drug users in treatment, it may underestimate the actual heroin-using population.

Methods

The study protocol was approved by the Ethical Review of Research Committee of the Thai Ministry of Public Health. A two-sample capture–recapture method was used.[11,12] The first capture was of all persons who were enrolled in methadone treatment programs for opiate addiction during the period April 17 through May 17, 1991, at the 17 clinics and at Thanyarak Hospital. For Thanyarak Hospital, only Bangkok residents and only those on outpatient treatment or those discharged from inpatient treatment were included. A confidential list was compiled containing forename and surname, gender, age, date of birth, Thai national identification number, and date of last methadone treatment.

The recapture was conducted from June 3 through September 30, 1991. Study teams made 891 visits on 66 days to 72 police stations in all areas of Bangkok. Included in the survey were persons held at police stations who had been arrested within the previous 72 hours. Urine samples were collected and the following information was recorded confidentially: forename and surname, gender, age, date of birth, Thai national identification number, and reason for arrest. Urine was tested by enzyme immunoassay for the presence of opiate metabolites (Emit d.a.u. Opiate Assay, Syva Co, Palo Alto, Calif) and methadone (Emit d.a.u. Methadone Assay, Syva Co, Palo Alto, Calif). The cutoff for positive, 300 ng/mL, was recommended by the manufacturer and was described as being 100% predictive of the presence of these substances. Information on persons with urine tests positive for opiate metabolites or methadone was included on a list for further analysis.

Information collected in the lists from the two captures was entered twice into a computer database in the Thai language. After keypunch errors were corrected, duplicate entries were removed from each list by means of a combination of computer sorting and visual inspection. The two lists were then merged, computer sorted by multiple variables, and visually inspected to identify the same entries (matches) in both lists. Criteria used to determine matching entries are shown in Table 1. Names were considered similar if they contained only minor spelling differences that did not change the name. This definition was established in view of the complexity of the Thai alphabet, which consists of 44 consonants, 32 simple and compound vowels (some written as super- or subscripts or combinations), and 4 tone markers. Dates of birth were considered similar if they varied by no more than one digit.

An estimate of the total population of opiate users (n) was made with the formula:

$$\text{Estimate of } n = \hat{n} = \frac{c_1 c_2}{m},$$

where c_1 and c_2 are the numbers of persons in the first and second capture,

TABLE 1—Criteria Used to Determine Matching Persons in the Two Captures and Number of Matches Identified for Each Match Type

Match Type	No. of Matches	Forename	Surname	Age	Date of Birth	Thai ID Number
A	9	Same	Same	Same	Same	Same
B	65	Same	Same	Same	Same	...
C	52	Same	Same	Same	Similar	...
D	45	Similar/same	Similar/same	Same	Similar/same	...
E	4	Different	Similar/same	Same	Similar	...
F	15	Similar/same	Similar/same	Different	Different	...

Note. Gender was the same for all match types.

TABLE 2—Reasons for Arrest for Persons Included in the Second (Police Arrest) Capture (n = 1540)

Reason for Arrest	No.	%
Marijuana-related	833	54.1
Heroin-related	421	27.3
Gambling	99	6.4
Robbery	73	4.7
Inhalant use	49	3.2
Assault	10	0.6
Other	55	3.6

respectively, and m is the number of persons identified in both captures (matches).[13] The following formulas were used to calculate the variance (Var) and 95% confidence interval (CI) for the estimate of n:

$$\text{Var}(\hat{n}) = \frac{c_1 c_2 (c_1 - m)(c_2 - m)}{m^3}$$

$$95\%\ \text{CI} = \hat{n} \pm 1.96\sqrt{\text{Var}(\hat{n})}.$$

These formulas[13] were also used to determine age-stratum–specific estimates of n. Stratum-specific estimates of n and variances were then summed to determine the total n and 95% confidence interval.

Population rates were calculated using 6 million as the total Bangkok population and 1 244 000 (20.7%) as the number of 20- through 39-year-old male Bangkok residents.[14]

Results

In the first capture, 4064 persons remained on the list after 478 duplicate names were removed. The mean age was 32.5 years (SD = 7.7); 34.0% were aged 20 through 29 years; 52.0% were aged 30 through 39 years; and 93.6% were male. Name and gender were recorded for all persons; also recorded were age for 99.7%, date of birth for 88.3%, and national identification number for 79.9%.

In the recapture, 8212 persons were surveyed at police stations. Included on the list (following the removal of 105 duplicate names) were the 1540 (18.8%) persons whose urine tests were positive for opiate metabolites (1513 [98.2%]) or methadone (198 [12.9%]); 171 (11.1%) were positive on both assays. The mean age of those with positive urine tests was 29.8 years (SD = 7.0); 45.4% were aged 20 through 29 years; 41.8% were aged 30 through 39 years; and 94.3% were male. Name and gender were recorded for all persons; also recorded were age for 99.9%, date of birth for 94.3%, and national identification number for only 2.8%. The reasons for arrest are shown in Table 2. Reportedly, persons possessing heroin were commonly charged with marijuana possession to expedite processing at police stations.

Match types A through D (Table 1) were considered to be true matches. By this standard, comparisons of the two lists identified 171 matches, yielding an estimate of 36 600 (95% CI = 31 538, 41 662) opiate users in Bangkok in 1991 (Table 3). Since the age distributions in the two captures were different ($P < .01$), a stratified analysis by age groups was conducted, yielding an estimate of 36 376 (95% CI = 30 996, 41 757) opiate users.

Various criteria were used to estimate n (Table 4). Using more restrictive (more specific) matching criteria by excluding type D matches increases the estimate of n by 35.7%, to 49 671. Conversely, using less restrictive (more sensitive) criteria by including type E and F matches decreases the estimate of n by 10.0%, to 32 940.

An estimate of 32 574 injection drug users (5 per 1000 persons in the total Bangkok population) results from the use of existing data indicating that 89% of opiate users seeking drug treatment in Bangkok inject the drugs.[1] However, since 94% of injection drug users are men and 87% are aged 20 through 39 years, the rate of injection drug users among men aged 20 through 39 years is 21 per 1000. Data from drug treatment programs indicate that roughly one third of all opiate users were HIV-1 seropositive in 1991[2]; it is likely that all were injection drug users, resulting in an estimate of approximately 12 000 injection drug users infected with HIV-1 (2 per 1000 total population). The rate of HIV-infected injection drug users among men aged 20 through 39 years is 8 per 1000.

Discussion

In 1991, it was estimated that there were 300 000 HIV-infected persons in Thailand.[2] Epidemiologic evidence suggested that the majority of these infections resulted from heterosexual transmission[2]; however, limited data were available to estimate the number of HIV-infected injection drug users. Capture–recapture methodology can be used to estimate the size of difficult-to-count subpopulations, although the reliable use of this method is not easily achieved.[15,16] It was possible to use this method in Bangkok, in part, owing to the availability of drug treatment and the great variety of Thai names.

Interest in enumerating injection drug user and prostitute populations, because of their increased risk for HIV transmission, recently led the World Health Organization's Global Programme on AIDS to review capture–recapture methods.[17] These methods have been used extensively in biologic sciences to enumerate animal populations[18,19] and have been used in the United States to evaluate the completeness of national reporting systems for congenital rubella syndrome[20] and mortality due to tetanus[21] and pertussis.[22] The numbers of drug users in Amsterdam,[23] in two boroughs of London,[24] and in Rome[25] have been estimated by a two-capture method. More recently, a multiple-recapture method was used to estimate the numbers of injection drug users[26–28] and female street prostitutes[29] in Glasgow, Scotland. Four major assumptions must be satisfied for the two-capture method to produce reliable results.[11,12,30]

The first assumption is that the population is closed. In reality, no city is closed and this assumption can only be

satisfied to a reasonable degree. If the population of opiate users is very dynamic, with members entering and leaving with great frequency, the recapture will be less likely to include persons identified in the first capture, resulting in a falsely low number of matches and an overestimate of the population of opiate users. To allow for the assumption that the opiate user population was reasonably stable during the study period, we limited the duration of the study to less than 6 months. Although we could not determine the number of opiate users who entered or left the city, it is unlikely that a substantial proportion did so during this brief period.

The second assumption is that the capture sources are independent. There is no clear positive or negative dependence between receiving methadone treatment and, at a later time, being arrested. The two captures were conducted sequentially with a 2-week period between them to allow for persons receiving methadone treatment in April or May to be at risk for arrest in June through September. The urine testing employed in the recapture permitted the detection of persons from the first capture who had either continued methadone or stopped methadone while using opiates. It could be argued that persons receiving methadone treatment have a decreased need for heroin (and therefore money) and are therefore less likely to be involved in criminal activity that would lead to arrest (negative dependence). However, in the second (police arrest) capture, we identified 198 persons with urine tests positive for methadone, 171 (86.4%) of whom were also positive for opiate metabolites. Conversely, one could argue that persons who receive methadone treatment are more likely to be arrested because of their increased likelihood of being identified as drug users by the police (positive dependence); however, we found no evidence that this occurred. The assumption of independence among captures is not required if more than two captures are employed; log-linear modeling is used to account for dependence among the captures.[13] In Bangkok, we were unable to identify a practical source for a third capture.

The third assumption is that all members of the population have the same probability of being captured. Free methadone treatment is available to all opiate users in Bangkok. All opiate users have a probability of seeking drug treatment and therefore of having been identified in the first capture; however, it is likely that there is a subgroup of opiate users, perhaps defined by socioeconomic status, with a decreased probability of seeking treatment. All opiate users have an appreciable probability of being arrested because heroin use in Thailand is illegal and highly associated with prison history.[1] The extensive scope of the police arrest recapture ensured a wide sampling of arrested persons in the city. Our finding that 34.0% of persons included in the methadone treatment capture, compared with 45.4% in the police station capture, were 20 through 29 years old suggests a difference in sampling for the two captures. Although an analysis stratified by age group yielded an estimate very similar to the overall estimate of the number of opiate users (Table 3), it is possible that other important strata remain unidentified and may contribute to a biased estimate.

The fourth assumption is that the capture history of each member is accurate: all true matches and only true matches are identified. The use of urine testing in the recapture ensured a highly specific identification of recent opiate users. Matches from the two capture lists were identified primarily by name, age, and date of birth. Gender was male for 94% of persons on both lists, and Thai national identification number, which was available for 79.9% of the persons on the first capture list but only 2.8% of those on the second list, was of limited value in matching. The great diversity of Thai names contributed to the specificity of the matching. Thai surnames, in the large majority of cases, are unique to each family and consequently are highly varied; thus it is extremely rare for two people to share the same forename and surname. Names reported to drug treatment programs are obtained from national identification cards and are therefore very accurate. The names reported at police stations generally are not verified by identification cards but are found to be largely reliable.

This study generated an estimate of the number of active opiate users in Bangkok at one point in time. Because we did not address the duration of injection drug use, we cannot estimate the number of persons in Bangkok who had ever injected drugs but who were not currently using heroin. However, a recent study of injection drug users in treatment in Bangkok found the average duration of use to be more than 8 years; only 11% had

TABLE 3—Estimates of the Number of Opiate Users in Bangkok (n), by Unstratified and Age-Stratified Analyses

Age Group	Capture 1	Capture 2	No. of Matches	n	95% Confidence Interval

[a]Matches were determined according to the criteria shown in Table 1.

started injecting within the previous 2 years.[1] Because extensive HIV-1 transmission among injection drug users in Bangkok began only in 1988, these data indicate that most injection drug users infected with HIV are included in our estimate of 12 000, based on the estimated population of 36 600 active opiate users.

HIV-1 seroprevalence among opiate users in Bangkok has been measured only among those who seek treatment. Insufficient data are available to determine whether HIV-1 seroprevalence among injection drug users seeking treatment in Bangkok differs from the rate among those who do not seek treatment. Nevertheless, as a substantial number of injection drug users enter the treatment population each year, the stability of HIV-1 seroprevalence documented from 1988 through 1993 supports the assumption that such a difference is unlikely to be great.

We estimate that there were 36 600 active opiate users in Bangkok in 1991, leading to an estimate of approximately 12 000 HIV-infected injection drug users, including 0.8% of all men aged 20 through 39 years. Through 1992, 1675 cases of AIDS had been reported in Thailand (population 55 million) via a well-established surveillance system; 1150 cases (69%) were reported in 1992 alone, indicating a rapid increase in AIDS cases. In 1992, injection drug users accounted for 103 (9%) of new AIDS cases (Division of Epidemiology, Thai Ministry of Public Health, unpublished data). In the coming years, the number of cases of AIDS and other HIV-related diseases, including tuberculosis, arising from the present HIV-infected population of injection drug users will rise dramatically, placing new demands on existing health care facilities. Controlling HIV transmission among members of this population and their sexual partners will be important in limiting the AIDS epidemic in Bangkok. □

Acknowledgments

This paper was presented in part at the Eighth International Conference on AIDS/Third Sexually Transmitted Disease World Congress, July 19–24, 1992, Amsterdam, the Netherlands.

We thank Dr Roel A. Coutinho, Dr J. Arthur Woodward, Dr Vichai Poshyachinda, Dr Robert Byers, and Mark VanLandingham for their guidance in developing this study and Drs Timothy J. Dondero, Phillip Nieburg, and Glen A. Satten for reviewing the manuscript. We are grateful to Police Lt Gen Chavalit Yodmani, Dr Suchint Phalakornkule, Dr Sithaman Muttamara, Dr Kowit Wongpanich, Dr Suwat Chanchamnong, Dr Sudchai Panyarachun, Dr Thamnoon Vaniyapong, Dr Prawat Pisesskolkit, Dr Virasak Vachatith, Dr Wonchat Subhaturas, Dr Sittichat Puttiprasert, Dr Jidbhong Jayavasu, and Dr Pralom Sakuntanaga for their invaluable support. We also thank Siree Bunnag, M.L. Araya Sirodom, Vichet Puthaviriyakorn, Warunyupa Suwannadath, Sathit Sujarita, Busakorn Wongsuwan, Dr Pongvipa Lohsomboom, Dr Boondee Atikij, Baranee Mingmuang, Janjao Witta, and Mancharee Junk for their assistance in conducting this study. In addition, we are indebted to the staff of the Department of Health, Bangkok Metropolitan Administration, and the Technical and Research Section, Office of the Narcotics Control Board, for data and specimen collection; the laboratory staff of Thanyarak Hospital for specimen testing; and the personnel of the Bangkok Police Department for their cooperation.

We are grateful to Albert L. Bryant and Robert D. Griffiths and acknowledge the Narcotics Affairs Section of the US Embassy in Bangkok for financial support toward the cost of urine testing reagents.

Call for Abstracts for Epidemiology Late-Breaker Sessions

Oral Exchange Session

The Epidemiology Section will sponsor a late-breaker epidemiology oral exchange session on Wednesday, November 2, 1994, during the American Public Health Association's annual meeting October 30 through November 3 in Washington, DC. The exchange will provide a forum for the oral presentation of investigations, analyses, or methods that have been conceived, conducted, and/or completed so recently that authors could not meet the deadline (February 10, 1994) for regular submission to other epidemiology sessions.

Abstracts of fewer than 200 words (any format) and a stamped, self-addressed return envelope should be submitted to Polly A. Marchbanks, PhD, Chief, EIS Program, Centers for Disease Control and Prevention, Mailstop C-08, 1600 Clifton Rd, Atlanta, GA 30333; (404) 639-3588.

Abstracts must be *received* by September 12, 1994. Decisions will be made by September 19, 1994.

Poster Session

The Epidemiology Section will again sponsor a late-breaker poster session on Wednesday, November 2, 1994, at the APHA annual meeting October 30 through November 3 in Washington, DC. This session permits the presentation of work that has been completed too late in the last year for regular paper submission. Abstracts should report on work conducted during the last 6 to 12 months.

With a stamped, self-addressed return envelope (or e-mail return address), abstracts of less than 200 words (any format) should be submitted to Cathey Falvo, MD, MPH, Graduate School of Health Sciences, New York Medical College, Valhalla, NY 10595; tel (914) 993-4323; fax (914) 993-4434; falvo@nymc.edu (internet).

Abstracts must be *received* by September 12, 1994. Decisions will be made by September 19, 1994.

Self-Rated Health and Survival: A 7-Year Follow-Up Study of Australian Elderly

John McCallum, DPhil, MPhil, Bruce Shadbolt, PhD, and Dong Wang, BSc

ABSTRACT

Objectives. This study tested the hypothesis, from North American findings, that global self-ratings of health predict survival for older Australians.

Methods. A stratified sample of Australians 60 years of age and older surveyed in 1981 was resurveyed in 1988. Cox proportional hazard general linear models were constructed separately for men and women to predict survival over 7 years.

Results. Better self-ratings of health had an incremental association with survival for women, but only men with poor ratings had significantly worse survival than others. After major illnesses, comorbidities, disability, depression, and social support were controlled for, poor ratings of health for both men and women were not significantly different from excellent ratings in predicting survival. Only women's good and fair health ratings remained significant predictors.

Conclusions. People rate their health as poor on the objective basis of illness and disability. Australian findings show gender differences relative to North American results; methodological differences and site and gender variability in health profiles are discussed as reasons for the varying results. (*Am J Public Health.* 1994;84:1100–1105)

Introduction

Global self-ratings of health are simple survey instruments, but evidence is growing that they are powerful, independent predictors of survival among the aged. In an article published in the *American Journal of Public Health* in 1982, the researchers of the Manitoba Longitudinal Study on Aging[1] first reported that self-ratings of health predicted survival independent of objective health status indicators. Self-ratings of health had been used as an economical substitute for clinical assessments,[2,3] but the Manitoba result showed that self-rated health predicted survival in its own right. Sociological claims that even ungrounded beliefs have real effects[4] and that health beliefs determine health outcomes[5] were given credence by the result.

An editorial[6] in the same issue raised concerns about the effectiveness of controls for health status. Subsequent US studies using data from different sites (Alameda County in California[7]; New Haven, Conn[8,9]; and Iowa and Washington counties in Iowa[8]), along with the first National Health and Nutrition Examination Survey (NHANES I),[10] the Longitudinal Study on Aging, and a study conducted in Kiryat One, Israel,[12] further tested the relationship between self-ratings of health and survival. Increasingly complex models with ever richer measures of health and other predictors of survival found, with the exception of NHANES I, that self-rated health remained a significant, independent predictor of survival.

Theoretical explanations followed rather than led the investigations. It was proposed that, while older people take account of medical information in self-assessments, health experts do not take account of psychosocial factors or subjective well-being in their assessments.[13] When a wide range of psychosocial and well-being measures were included in the new studies, the self-rated health effect remained significant, indicating that the relationship between self-rated health and survival is independent of psychosocial measures whether or not they enter into physicians' diagnoses.

Three specific explanations have been proposed.[14] First, negative perceptions can stimulate the release of chemicals that compromise the immune system (the psychoneuroimmunological explanation). Second, poor self-perceptions may derive from self-detection of health conditions in preclinical phases. Third, these perceptions may be associated with delay or resistance in taking actions to protect and maintain one's health.

These explanations do not find consistent support in existing results. First, the lack of significance of depression in various models is inconsistent with a psychoneuroimmunological explanation. Second, in NHANES I,[10] self-ratings of health predicted early and late mortality equally well; thus, it was unlikely that personal knowledge of undiagnosed conditions explained the mortality prediction. Third, studies with extensive risk factor behavior controls[8,9] also showed that the effect is independent of risky health behaviors. Consequently, Idler and Kasl concluded that health perceptions have direct and independent effects on survival but that these effects work through un-

known processes: "Health perceptions may represent a unique construct, and a unique process, not reducible to other already known constructs and processes."[8]

While existing discussions have stressed the consistency of the observed relationship between self-ratings of health and survival, results by site and gender have been inconsistent across studies in some details. The NHANES I analysis reported that self-rated health was associated with survival over a 12-year period among middle-aged men but not among elderly men or women. Possible reasons offered for the lack of results for the 65- to 74-year age group were the more extensive list of physician diagnoses and risk factor measures and the use of a heterogeneous national sample. In Iowa,[9] only the extreme poor/bad categories remained significant for women, and only the poor/bad and fair categories remained significant for men. Only two of the seven investigations mentioned earlier, the Alameda County study[7] and the Longitudinal Study on Aging,[11] showed larger adjusted odds ratios for women than men for the worst self-rated health category included. The Kiryat One results[12] from Israel matched those from most US studies with significant adjusted odds ratios that were larger for men than for women.

Variability by site and gender is consistent with the fact that self-assessments have no absolute reference point. People use personal, peer group, and objective medical information to make a global assessment. It follows that self-ratings of health can be based on different information for men and women at different phases of the life cycle and in different social contexts. This raises the question addressed here: Will self-rated health predict survival in a similar way among elderly individuals residing in Australia?

Methods and Data

Hazard of death was analyzed as a response variable to baseline self-assessments of health. After examination of how well self-rated health predicted survival, adjustments were made for various confounding factors. Survival analyses were conducted in LIMDEP[15]; regression was used as a partial likelihood procedure to model risk. On the basis of Cox[16] proportional hazards, inferences can be made about the risk multiplier $g(x)$ without involving the function $l(t)$, which provides the underlying shape of the variation of hazard with time. The hazard of death at time t, denoted by $h(t, x)$, is dependent on covariables denoted by x, as follows:

$$h(t, x) = l(t)g(x).$$

The analysis used data from the Ageing and the Family Project Survey.[17] This survey, conducted in November 1981, involved interviews with a random sample of 1050 people living in Sydney, Australia, who were 60 years of age and older. After enumeration of households in randomly selected districts, eligible respondents were stratified by age and living arrangements. The sample strata were designed to oversample very old people not living with other older people: 25% of persons 60 through 64 years of age were sampled, along of with 50% of those 65 through 74 years of age, 50% of those 75 years of age or older if they lived with someone else 60 years of age or older, and 100% of those 75 years of age or older if they did not live with someone 60 years of age or older.

In 1988,[18] a follow-up questionnaire was administered to the survivors from 1981. People who died over the 7-year period (22% of respondents) were identified from state death records and their dates of death recorded. Seventy percent of the respondents participated in the 1981 baseline survey, 87% of whom agreed to follow-up. The status of 91% of the follow-up respondents was determined, and the 9% who were untraceable were excluded from analyses. Analysis of dropouts indicated no significant biases by age, sex, or other major demographic characteristics.

Measures

Self-rated health was measured by the question "Would you say your overall health is excellent, good, fair, or poor?" Three dummy variables were used to compare the latter three states with "excellent."

Controls for age (5-year groups) and living with someone 60 years of age or older were necessary in dealing with the sample strata. The few interviews conducted by proxy because of frailty or language difficulty were controlled by use of a dummy variable.

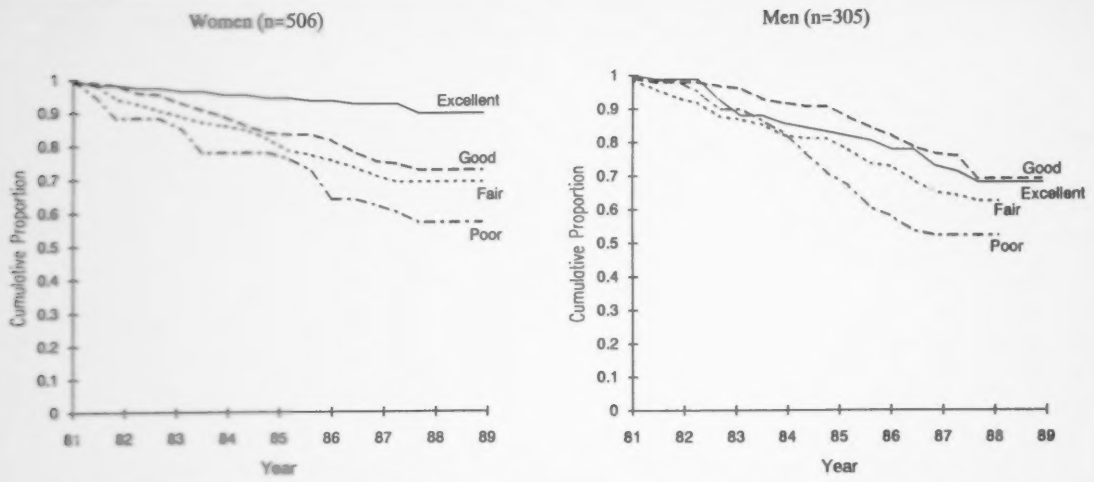
Various other measures were included in models to examine confounding effects on self-rated health and survival. First, the marital status categories widowed, never married, and divorced/separated were compared with married status. Possible confounding survival advantages reported for married people may be a consequence of either "health selection" of people into marriage or "social causation" during marriage.[19]

Older people born in Greece and Italy were identified by a dummy variable. About 35% of the Australians 65 years of age and older were born overseas, including some who were members of immigrant groups with survival advantages. The most notable group was that composed of Greek- and Italian-born immigrants, who had a lower risk of coronary heart disease and some cancers.[20] Other immigrant groups had very small numbers or no survival advantage.

Ownership of a private dwelling, a general indicator of wealth, relief from rent, and income, was used here as a single variable to control for possible confounding effects of class and income. Social class measures have been shown in Australia to have an inverse association with survival,[21] but this class effect disappears with age.[22] Income-based measures of class among the elderly are affected by the flat-rate Australian retirement income system and provide poor indications of lifelong advantages.

To control for objective health status, respondents were asked "Have you had a serious illness or accident in the past 5 years? What was that?" Survey respondents generally provide accurate reports of their health status, except when a disease is diagnostically complex.[23-25] Sufficient numbers of our respondents reported circulatory, respiratory, and musculoskeletal conditions; neoplasms; and falls. The remaining diseases reported were classified as "other," and the null category for comparison was the absence of a condition in the last 5 years. People who reported more than one serious illness in the last 5 years were defined as having a serious comorbidity unless one of the illnesses was musculoskeletal. Whether someone had been ill in bed at home in the last 6 months was also used as a dummy variable for minor and undiagnosed illness.

Disability was measured by a mix of items focusing on activities of daily living and instrumental activities of daily living, including bathing, doing housework, climbing stairs, going out of the house, using public transportation, and being able to walk half a mile. A composite measure of functional health was constructed by



Note. The proportions surviving have been adjusted for variations in the age structure of the samples by means of direct standardization, in which the age distribution of women exposed at the baseline survey who rated their health as excellent is the standard.

FIGURE 1—Age-standardized cumulative proportions of survival over the study period within each self-rated health group (Excellent, Good, Fair, and Poor).

adding one point for each item performed without difficulty.

Depression was measured with the Philadelphia Geriatric Center Morale Scale.[26] Because a connection has been observed between depression and survival, depression was a potential confounding factor; however, there is controversy about its causal direction.[27-29] Depressed (2 to 8 symptoms) and very depressed (9 to 12 symptoms) respondents were compared with those with no symptoms or 1 symptom. The missing values on the 12-item morale scale were modeled as a separate category.

The effects of social support on mortality are well established,[30,31] and these effects were other potential confounders in this study. Three indicators of emotional support were used: having someone to confide in, having someone who makes you feel needed, and having someone with whom you share common interests. Since all three measures had high positive intercorrelations, a composite emotional support measure was constructed by adding a point for each positive response. Social participation was indicated by four items: having someone come to visit, going out to visit others, going on outings and social gatherings with others, and attending clubs and other social organizations. A composite measure of social participation was constructed by assigning each positive answer a score of 1.

Results

Overall, 76% of women, in comparison with 67% of men, survived the follow-up period. Figure 1 shows that, after standardizing for age, the relationship between self-rated health and survival was relatively well ordered for women; for men, however, only the poor rating was clearly different from others. Men, especially those with excellent self-rated health, showed a lower probability of survival than did women. Men with good ratings had survival probabilities similar to those of men with excellent ratings.

The results in Figure 1 justified further analysis of the effects of self-rated health after controlling progressively for a broad range of factors that predict survival. For women (see Table 1), the addition of sample characteristics and demographics (model 1) did not significantly alter the relationship between self-rated health and survival; mortality risks increased incrementally with poorer self-ratings of health. The relative risks (exponentiation of the regression parameters) were 3.2 (95% confidence interval [CI] = 1.6, 6.5) for good vs excellent, 3.8 (95% CI = 1.8, 7.9) for fair vs excellent, and 5.3 (95% CI = 2.4, 11.7) for poor vs excellent. After controlling for serious illnesses and accidents (model 2), self-rated health remained a significant predictor, but the relative risk associated with poor self-rated health was reduced to 3.2 (95% CI = 1.3, 7.4). Controlling for disability (model 3) further reduced the effect for poor self-rated health to the point at which it was no longer significant at the .05 level. Depression did not add significantly to model 4, but emotional support was significant. The relative risks of death for women in model 4 were 3.2 (95% CI = 1.5, 6.7) for good vs excellent, 2.4 (95% CI = 1.1, 5.2) for fair vs excellent, and 1.9 (95% CI = 0.7, 5.1) for poor vs excellent.

For men (see Table 2), after controlling for sample characteristics and demographics (model 1), only the coefficient for poor self-rated health was significantly different from that for excellent self-rated health. Men's relative risks were 0.8 (95% CI = 0.4, 1.4) for good vs excellent, 1.5 (95% CI = 0.8, 2.7) for fair vs excellent, and 3.1 (95% CI = 1.7, 5.8) for poor vs excellent. The result for the good self-rated health category indicates that men with good ratings had a lower (but nonsignificant) risk than the baseline

*$P < .05$; **$P < .01$; ***$P < .001$.

hazard for men with excellent ratings. After controlling for serious illnesses and accidents (model 2), self-rated health remained significant, but the relative risk for poor self-rated health was reduced to 2.6 (95% CI = 1.2, 5.5). Controlling for disability (model 3) further reduced the relative risk for poor self-rated health to the point at which it was no longer significant at the .05 level. Depression and social support did not significantly add to model 4. The relative risks for men in model 4 were 0.8 (95% CI = 0.4, 1.5) for good vs excellent, 1.1 (95% CI = 0.6, 2.2) for fair vs excellent, and 1.7 (95% CI = 0.7, 4.3) for poor vs excellent.

The addition of the blocks of factors to the models (shown in Tables 1 and 2) made a significant contribution to log likelihood differences in each case, except for the additions to models 3 and 4 for men. The log likelihood values without self-rated health (calculated for each model by excluding self-rated health dummies) further show that self-rated health dummies added significantly to all models except models 3 and 4 for men.

Discussion

The results confirm that self-rated health is related to survival for older Australians. The finding that the survival effects of poor ratings of health were explained mostly by serious illnesses and disability is consistent with the model of health status recently specified by Johnson and Wolinsky.[32] They reported evidence for a natural progression of effects from body to mind as diseases take their toll on activities of daily living and dampen the perception of good health. Thus, the effects of poor ratings observed here fit a medical model of survival.

There was, however, variation in the effects of intermediate ratings between Australian men and women. After the addition of controls, men's ratings did not

differentiate the risks of survival. The persistence of effects on survival of women's good and fair ratings, after the fitting of controls, adds a degree of complexity to the model. Australian women appear to use information that is not used by men for the intermediate ratings. The addition of healthy life-style indicators to the model (not available here) may reduce the effects of these intermediate categories for women.

These findings add to the existing evidence of variability in North American studies. For example, no effects after fitting controls were observed for the 65- to 74-year age group in the NHANES I analysis,[10] and, in Iowa,[9] the poor/bad and fair ratings were significant for men, but only the extreme poor/bad rating was significant for women. Furthermore, in this study relative risks were higher for women than for men, a finding similar to that of only two existing studies.[7,11]

How are the different findings between studies to be explained? Three possibilities are different methods, different health profiles for populations, and different health perceptions by sex and sites. The study methods differ in specific questions used and response categories, length of follow-up, statistical methods, and sampling strategies. Nonetheless, studies indicate general consistency in the relationship between self-rated health and survival. However, the Longitudinal Study on Aging authors[11] noted that men's results are best behaved in studies that use the extreme category "bad" rather than the poor category. Consistency in methods is a desirable goal for future studies of the relationship between self-ratings of health and survival.

As a result of different sex role socialization and cultures, differences may exist between sites in the ways that people combine different types of disease and disability information to make self-assessments. The concentration in existing studies on simple global assessments needs to be supplemented by testing of detailed models of the process of self-

assessment such as the model proposed by Johnson and Wolinsky.[32] On the basis of the results of this study, it would be expected that such processes differ systematically by gender and site.

Furthermore, self-rated health can embody actual differences in health information (e.g., men and women have different "objective" health profiles, as do people in different areas). National data for older Australians in 1981 and 1988 showed that death rates for coronary heart disease were two to three times higher among men than among women.[33] The dominant risk factors for coronary heart disease, such as smoking and hypertension, have large effects for men. For women, for whom single risk factors are not dominant, more variables with smaller coefficients reach significance in the model.[34] The prevalent, acute nature of heart attacks for this cohort of men may create the basis for less gradation in men's self-ratings with respect to survival relative to women and the better match of Australian men's perceptions of poor health to a "medical model."

The persistent effect of self-rated health among the elderly despite extensive health controls may be due to the inability of medical and social science to adequately model the complex, multiple, interacting illnesses of elderly people. It is known that risk analysis does not account for frailty (the problem of many variables each contributing individually a small amount to total variability but together making a significant difference).[35] We await statistical developments in the measurement of frailty to test this possibility.

Also, there are no economical survey measures of system aging or senescence (system failure distinct from failure of body parts and specific illness) independent of chronological age. Hence, senescence is generally omitted from health status models. The possibility that self-perceptions indicate frailty or senescence suggests that it is not yet time to claim that the self-rated health effect is unique and the process unknown.[8] Senescence may well be better recognized by aging people than by any existing survey measures.

The two interests in self-ratings of health are confirmed by Australian evidence for the elderly. First, self-rated health is an economical indicator of health defined by severe illnesses and disability. Second, it adds finer-graded information about health related to survival, but only for women. The specific variability observed in Australian and other findings points to the need for more research to explore the structure of health status among older adults. □

Work-Related Traumatic Brain Injury in Washington State, 1988 through 1990

ABSTRACT

Objectives. Brain trauma is a major cause of disability in the United States, especially among young adults. Work-related brain trauma cases represent a subpopulation that may be amenable to intervention efforts, but largely because of unavailability of data, this group has not previously been studied.

Methods. Washington State workers' compensation data were used to identify brain trauma cases and to describe incidence rates with respect to age, gender, and industrial classification. Cause of injury was evaluated for industrial classifications with numerous cases.

Results. Washington State workers experienced 301 brain traumas over a 3-year period (9.4/100 000 full-time-equivalent workers per year). One third of all traumatic brain injury claims were concentrated among seven industrial classifications. Cause of injury was highly correlated with specific industrial classifications.

Conclusions. This study demonstrates the usefulness of diagnosis-related group codes to identify cases of traumatic brain injury. These injuries are concentrated among a few industries, with a dominant specific cause for each industry. This suggests that intervention methods may be efficiently introduced to reduce traumatic brain injuries in the workplace. (*Am J Public Health.* 1994;84:1106–1109)

Nicholas J. Heyer, PhD, and Gary M. Franklin, MD, MPH

Introduction

Brain trauma is a major cause of disability, especially among young adults. The costs of brain trauma in the United States were estimated at $4 billion in 1980.[1] Although many studies have generated traumatic head and/or brain injury incidence rates for general populations,[2] none have focused on persons with work-related brain trauma as a subpopulation potentially amenable to prevention and control efforts.

The dearth of information on work-related brain trauma is most likely related to the difficulty in identification of these cases. Occupation codes associated with hospital discharge data and death certificates are typically underreported or unreliable. One US study[3] reported that 4.4% of all brain traumas (7.3% of those rated as severe) were work related. In this population-based study, Annegers et al.[3] used the unique records-linkage system of the Mayo Clinic in Rochester, Minn, to identify cases; however, skull fractures without brain injury were included, and criteria for work-relatedness were not described. A Norwegian study using similar case definitions reported that 4.8% of incident brain trauma cases were work related.[4]

We used an administrative database from the Washington State workers' compensation system to determine: (1) the most useful codes for ascertainment of hospitalized brain trauma cases (e.g., diagnosis-related group [DRG] codes; *International Classification of Diseases,* Ninth Revision [ICD-9], codes; or American National Standards Institute [Z16.2] codes); (2) age-, gender-, and industry-specific incidence rates of work-related hospitalized traumatic brain injury; and (3) whether industry-specific variability appears substantial enough for surveillance and targeted prevention efforts.

Methods

The Workers' Compensation Data System

The Department of Labor and Industries is the sole regulator of workers' compensation coverage for non-federally covered workers in Washington State. Approximately two thirds of these workers are covered through the State Fund; the remainder are covered through approximately 365 large companies that are able to self-insure. This study uses the extensive claim and medical bill payment information maintained by the Department of Labor and Industries on State Fund-covered workers. Data on workers covered by self-insured companies are inadequate for research purposes and are not included in this study.

The following selected variables from the Department of Labor and Industries database were reviewed: (1) Department claim data: age, gender, Z16.2 nature of injury codes, and industry codes (Washington Industrial Classification)[5]; and (2) Medical bill payment data: hospital ICD diagnostic codes, hospital DRG codes, and length of hospital stay. The DRG codes used are from Version 8 of the Medicare DRG grouper.

[a]Incidence rate per 10^3 FTE/year.
[b]Average length of stay in days—index hospitalization.
[c]Percentage with index hospitalization of only 1 day.

Case Definition

A case of traumatic brain injury was considered definite if any of the following were documented in the medical records in association with a head trauma: clinical or imaging evidence of brain injury, a medical diagnosis of concussion, or a clear description of loss and/or alteration of consciousness. A diagnosis of closed head injury or fracture with none of the above documented findings was not considered sufficient for inclusion.

Case Ascertainment

All State Fund-insured claims requiring hospitalization were identified for calendar years 1988 through 1990. Hospital DRG codes, hospital ICD codes (up to five codes), and Z16.2 codes for part of body injured were classified a priori to indicate possible traumatic brain injury cases. These codes were checked both singly and in combination for their specificity by a review of medical records from a representative sample of 40 claims.

Based on the review of claims, probable brain trauma cases were defined as those with a DRG specifying brain trauma and/or those with both ICD and Z16.2 codes specifying brain trauma. Final selection of claims for this study was based on the following criteria: (1) a review of the medical records for each probable claim identified by the case definition described above; (2) date of injury between January 1, 1988, and December 31, 1990; and (3) hospitalization within 7 days of the date of injury.

Age-, Gender-, and Industry-Specific Rates

Hours worked per year are reported for individual industry groupings (Washington Industrial Classification). Full-time-equivalent workers were calculated for each industrial class by dividing the total hours reported by 2000.[5] Hours reported by industry class are not reported by age and gender. Thus, denominators for age- and gender-specific rates were estimated from the 1990 census (Washington State Office of Financial Management). The proportion of the work force by age and gender was applied to the total number of hours reported to the Department of Labor and Industries.

Statistical Analysis

All rates were calculated as the number of incident brain trauma cases/100 000 full-time equivalents per year. Industry-specific rates were compared with the industrywide rate by using a rate ratio with a 95% confidence interval.[6]

Results

A total of 310 probable brain trauma cases met the date of injury and hospitalization within 7 days requirements of this study. A detailed review of these cases found that 301 qualified for this study. Table 1 shows the distribution of the 301 qualified cases as well as the 6 that were excluded for not meeting medical criteria, according to our DRG, ICD-9, and Z16.2 selection factors. All but 7 of the qualified cases would have been identified by DRG alone.

Based on 301 cases, the industrywide average annual incidence of work-related hospitalized traumatic brain injury was 9.4 cases/100 000 full-time equivalents (Table 2). The decline in hospitalized cases in 1990 is explained by a dramatic fall in the proportion of cases hospitalized for only 1 day.

Figure 2 shows the age-specific incidence for brain trauma injuries. The mean age of traumatic brain injury was 36 years (range, 14–75 years), with peaks of injury occurring in the 16–34-year and 55–64-year age groups. The incidence rate of brain trauma was 6.3 times higher for men than for women, the rate for men being 15.1 per 100 000 full-time equivalents and the rate for women being 2.4.

The majority of brain trauma cases resulted from falls (48.5%), from being struck by an object (26%), or from motor vehicle accidents (18.3%). The average length of the index hospitalization, a marker of case severity, averaged 6.8 days with little variation by external cause of injury (Table 3). Case severity appeared to be more clearly related to specific DRG codes (Table 4).

The seven industrial classifications with the highest number of traumatic brain injuries (six or more) accounted for one third (101/301) of all such cases (Table 5). Brain trauma cases tended to cluster by external cause of injury within industrial classes. For example, 85% (29/34) of cases in logging were due to being struck by an object, whereas 84% (21/25) of cases in wood-frame building construction, 86% (6/7) of cases in roof work, and 77% (10/13) of cases in orchard and dairy farms were due to falls from height. Also, 58% (11/19) of cases in trucking were associated with motor vehicle accidents. Industries with significantly elevated relative rates (RRs) include logging (RR = 36.7), roof work (RR = 17.1), garbage collection (RR = 13.5), street and road construction (RR = 12.4), trucking (RR = 10.0), dairy farms (RR = 8.9), interior finish carpentry (RR = 8.8), and building

construction (RR = 7.2). See Table 5 for a more complete listing of information.

Discussion

Using a workers' compensation administrative database, we identified 301 incident cases of work-related traumatic brain injury involving hospitalization for the years 1988 through 1990 in Washington State. The average annual incidence of hospitalized brain trauma was 9.4 cases/100 000 full-time equivalents. The marked excess of males (ratio of males to females = 6.3:1) and the secondary age peak in the 55–64-year age range differ from the distributions reported for the general population, where ratios of males to females are usually in the 2 to 3:1 range, and a secondary peak occurs after 65 years of age.[2] These differences are likely due to different distributions of occupational and nonoccupational risk factors, but may also be partly explained by differences in underlying population distributions.

The proportion of head injuries ascribed to an industrial cause has ranged from 4.4% to 4.8% in population-based studies[3,4] to 8% to 14% in studies from regional referral centers.[7–11] The age-adjusted annual incidence rate reported for work-related head trauma from Rochester, Minn, was 11/100 000, similar to the rate reported here specifically for brain trauma. In contrast to the Rochester study, the current investigation excluded cases of skull fracture that had no medical documentation of clinical brain injury.

Work-related brain trauma cases were most efficiently identified by hospital DRG codes. Both ICD and Z16.2 codes, alone and in combination, performed worse than DRG codes in terms of their unique contribution to case finding. DRG codes are related to prospective payment for hospitals and as such may be more accurately recorded. In addition, payment is strongly tied to expected duration of hospitalization for specific diagnostic categories. This precept was validated in this study; mean length of index hospitalization was strongly related to increasingly severe DRG categories. Patients with uncomplicated concussion averaged 3 days of hospitalization, whereas those with stupor lasting longer than 1 hour (but not requiring surgery) averaged 9 days in hospital.

As a prognostic marker of brain trauma severity, DRG codes may perform better than ICD codes. One prior study observed only 48% agreement between ICD codes and documented injury severity for head/neck injuries; ICD codes were far better in predicting severity of extremity injuries (74% agreement).[12] Further validation of the prognostic utility of DRG codes in predicting outcome of traumatic brain injury in population-based studies may be warranted. The most commonly used prognostic indicator of outcome, the Glasgow Coma Scale,[13] could not be reconstructed from the available medical record data in this study.

The mean length of stay for the index hospitalization reported here (6.8 days) is comparable to the length of stay reported in older studies[1,4] and may be a reasonable marker of injury severity.[14] The decline in rate of brain trauma admissions between 1988 and 1990 can be attributed entirely to a fall in 1-day hospital admissions. The proportion of such admissions fell from 30% in 1988 to only 2% in 1990. This decline is consistent with a sentinel effect related to recent, more restrictive Medicare billing policies for 1-day hospital admissions.

One third of all brain trauma cases occurred among only seven industrial classes. High relative risks were found for logging, roofing, garbage collecting, trucking, farming, and construction. External cause was related to industry type, so that falls were common in roofing, farming, and construction; motor vehicle accidents were common in trucking; and being struck by an object was the most common mode of injury in logging. Such clustering of traumatic brain injuries by external cause within industries and the large number of cases in relatively few industries provide an opportunity to target safety activities that would be a cost-effective method of preventing work-related traumatic brain injuries. Although work-related brain trauma most likely accounts for only 5% to 10% of all reported cases of traumatic brain injury, existing occupational safety and health resources could efficiently address this problem in the United States.

This is one of several recent studies undertaken to determine the usefulness of a workers' compensation database to generate population-based rates of work-related injuries.[5,15,16] Although there are some limitations to such studies (underreporting, misclassification), use of such extensive databases to clearly define variability among industries and thus to target further efforts at prevention and control is warranted. Our inability to access data on federal workers or on workers in the largest, self-insured companies would make extrapolation of the rates presented here to those venues difficult. The advantages of the Washington State system, excellent availability of diagnostic codes and of hours worked reported by industry class, have allowed an increased degree of specificity in studies using workers' compensation data. □

TABLE 5—Rates of Brain Trauma, by Industrial Class[a]: Traumatic Brain Injury, Washington State Workers' Compensation, 1988 through 1990

Industrial Class	FTE	Exp	Obs	Rate[b]	Relative Risk[c]	95% CI
Logging operations	9 849	0.93	34	345.20	36.69	25.42, 51.22
Roof work: all types	4 358	0.41	7	160.61	17.07	6.83, 35.17
Garbage collecting	3 932	0.37	5	127.16	13.51	4.36, 31.52
Street and road construction	6 003	0.57	7	116.62	12.39	4.96, 25.52
Trucking: interstate and intrastate	15 898	1.50	15	94.35	10.03	5.61, 16.52
Farms: dairy	7 191	0.68	6	83.44	8.87	3.24, 19.29
Interior finished carpentry	4 829	0.45	4	82.83	8.80	2.37, 22.56
Building construction: wood frame	36 701	3.45	25	68.12	7.24	4.69, 10.69
Electric wiring in building	17 755	1.67	5	28.16	2.99	0.97, 6.98

Maternal-Infant HIV Transmission and Circumstances of Delivery

ABSTRACT

Objectives. Circumstances of delivery among children with acquired immunodeficiency syndrome (AIDS) were investigated to assess whether they were consistent with predictions that intrapartum factors affect the risk of maternal-infant human immunodeficiency virus (HIV) transmission.

Methods. Pediatric AIDS patients (maternal-infant transmission; n = 632) reported to the New York City Health Department through 1991 were compared with a series of infants born to predominantly uninfected women. For each case patient, five control subjects were selected and matched from birth certificate files. Hypothesized case–control comparisons for mode of delivery and preselected complications were tested.

Results. Compared with control subjects, case patients were less likely to have been delivered by cesarean section without complications (odds ratio [OR] = 0.77; 95% confidence interval [CI] = 0.59, 1.01) and more likely to have been delivered with complications, whether delivery was by cesarean section (OR = 1.54; 95% CI = 0.98, 2.43) or vaginal (OR = 1.66; 95% CI = 1.15, 2.39).

Conclusions. Assuming that HIV-infected and uninfected women have comparable circumstances of delivery, conditional on sociomedical characteristics, these results suggest that intrapartum events may be associated with maternal-infant HIV transmission. (*Am J Public Health.* 1994;84:1110–1115)

Introduction

Knowledge of the timing of maternal-infant human immunodeficiency virus (HIV) transmission, whether in utero (and if so, at what stage of pregnancy) or at the time of labor and delivery, is critical to both an understanding of the mechanisms of transmission and the development of interventions aimed at preventing infection. Virus has been isolated from fetuses electively aborted early in gestation,[1,2] supporting the inference that at least some transmission takes place in the early intrauterine phase. However, laboratory diagnostic methods (viral culture and polymerase chain reaction) that have excellent sensitivity among older children and adults, if carried out in the neonatal period, identify only half of the children later known to be HIV infected.[3,4]

One explanation for this diagnostic anomaly is that at least half of maternal-infant HIV transmission actually occurs only at parturition; hence, infected cells are scarce at birth and take time to replicate to detectable levels. Further evidence in support of late transmission comes from a study of twins discordant for HIV infection, in which transmission was observed to be less likely for the second-born than for the first-born twin.[5] This finding has been attributed to a briefer exposure to virus in the lower genital tract during delivery of the second twin. Some epidemiological studies have found that babies born by cesarean section have lower rates of infection than babies born vaginally, although none of the individual studies reports statistically significant differences.[6–9] An increased risk of HIV transmission in more complicated deliveries was also observed.[8]

Based on these findings, we hypothesized that if maternal-infant transmission often occurs intrapartum, both mode of delivery and specific complications of delivery that increase or prolong the infant's exposure to maternal blood and secretions at delivery are likely to affect the risk of infection. Unlike other research undertaken to test these relationships, the present study is not based on a cohort of HIV-infected women followed to determine the infection status of their offspring. Such a design is, in principle, to be preferred but is difficult, given the large sample size needed. Instead, we pursue an indirect approach comparing the circumstances of delivery of children with acquired immunodeficiency syndrome (AIDS) reported to the New York City Department of Health with those of a series of uninfected infants born to predominantly uninfected women. If HIV-infected and uninfected women are assumed to be comparable with respect to their circumstances of delivery, conditional on sociomedical characteristics, this comparison should be informative about the association between circumstances of delivery and maternal-infant HIV transmission.

Methods

Of 951 children less than 13 years old diagnosed with AIDS as defined by the Centers for Disease Control and Prevention (maternal-infant transmission) and reported to the New York City Department of Health through 1991, 632 were linked to their New York City birth certificates. Matching criteria included identical or phonetically similar first and last names, identical date of birth, and same sex. Given concordance in other information except the child's last name, a match on the mother's last name was accepted. Failure to link could be owing to clerical or recording errors or name changes, or to births occurring outside New York City. The case patients who could be linked did not differ significantly from unlinked patients in terms of sex, ethnicity, and maternal drug use, but the former were more likely than the latter to have been diagnosed with AIDS before 1 year of age ($\chi^2 = 7.77$, $P = .005$) and less likely to still be alive ($\chi^2 = 3.12$, $P = .077$). This paper reports on the 632 case patients who could be linked, of whom 26% had been diagnosed with AIDS before the age of 1 year, 33% were still alive, and 58% had mothers who were recorded as using injection drugs.

An analysis data set without identifiers was produced combining data from the birth record and the AIDS case report. Data from birth records included mode of delivery (cesarean section or vaginal delivery), complications of labor and delivery, and obstetrical procedures. The delivery complications recorded on the birth certificate were reviewed to identify those likely to increase the risk of maternal-infant HIV transmission owing to the infant's increased or prolonged exposure to maternal blood and fluids. Based on this a priori review, the following complications were defined as risky: placenta previa, abruptio placentae, prolonged labor or failure to progress, premature rupture of membranes, excessive bleeding or hemorrhage, and abnormal presentation. Each case patient was categorized as delivered vaginally, by cesarean section, or by other/unknown mode, with or without the concurrent complications considered risky. A gradient was thus established in which vaginal deliveries without complications were considered the referent category. The study hypothesis predicted that children with AIDS would be the products of fewer cesarean sections without complications and a greater number of vaginal and cesarean deliveries with complications.

The birth certificate records also provided maternal sociodemographic characteristics (ethnicity, age, parity, education, marital status, financial coverage); medical risks during pregnancy (prenatal care, substance use, other medical conditions); and child outcomes (birthweight, gestational age, Apgar scores).

For comparison, five control subjects matched for race, year of birth, and institution of birth were selected from birth certificate files for each case patient. The delivery experience of these control subjects was classified as above, and items of their sociomedical profile were recorded.

The analysis was conducted as follows. First, the sociomedical profile and circumstances of delivery of the case patients and control subjects were compared and tested using chi-square tests. Second, among the control group only, independent associations (Mantel-Haenszel odds ratios [ORs]) between circumstances of delivery and maternal age, parity, education, marital status, prenatal care, financial coverage, drug use during pregnancy, medical risks during pregnancy, gestational age, and birthweight were investigated. Third, circumstances of delivery between both groups were compared within sociomedical strata. Stratum-specific odds ratios were calculated and chi-square tests for trend across the delivery categories within each stratum were performed. Finally, circumstances of delivery between both groups were compared, adjusted for sociomedical characteristics, using multiple logistic regression models. To take into account frequency matching in the data, dummy variables for the matching criteria were added to the logistic models.[10] They were excluded from the final models, however, as they did not change estimates of the regression coefficients.

Results

Maternal and Child Characteristics

A comparison of the maternal and child characteristics of the pediatric AIDS patients and the control group is presented in Table 1. Mothers of children with AIDS were older than comparison mothers and had higher parity. Within maternal age categories, parity remained higher among the case mothers. Case mothers had fewer years of education and were more likely than control mothers to be covered by Medicaid, to have received late or no prenatal care, and to be unmarried. Few of the mothers of either group had received optimal prenatal care, defined as a first visit in the first trimester followed by five or more visits. Case mothers were more likely to have had a sexually transmitted disease during pregnancy and were similarly likely to have had other medical complications during pregnancy, such as diabetes, anemia, preeclampsia, and other conditions. The reported use of substances during pregnancy, especially heroin and cocaine, was higher among mothers of children with AIDS. (A comparison of data on the AIDS case report and birth registry suggests that drug use may be underreported on the birth registry; however, the two data sources are not directly comparable as the birth certificate refers to substance use only during pregnancy. Data from birth certificates would have correctly identified only 29% [107/366] of women recorded on the AIDS case report to inject drugs.)

Children with AIDS had lower birthweights and displayed higher rates of prematurity than control children. Birthweights were lower among case patients independent of gestational age.

Complications and Mode of Delivery

Table 2 presents the frequency among case patients and control subjects of specific risk complications of delivery and mode of delivery. Among case patients, 17.9% were delivered by cesarean section (11.4% were primary and 6.5% were repeat cesarean sections) compared with 19.3% of control subjects (12.2% primary and 7.1% repeat). However, there were fewer cesarean section deliveries without complications among the case patients (13.3%) than among the control group (16.2%), and case patients accounted for an excess of both cesarean and vaginal deliveries with risk complications. Unadjusted for any sociomedical factors, case patients were more likely to have experienced complications during both vaginal (OR = 2.0; 95% confidence interval [CI] = 1.4, 2.8) and cesarean deliveries (OR = 1.5; 95% CI = 1.0, 2.3) and were less likely to have had cesarean deliveries without complications (OR = 0.8; 95% CI = 0.7, 1.1) than control subjects.

From birth certificates, a similar proportion of mothers of AIDS patients (6.6%) and control subjects (6.8%) had had a previous cesarean section. Among the 253 who reported a previous cesarean section, 72.5% of case mothers and 80.3% of control mothers had a cesarean deliv-

ery in the index pregnancy (OR = 0.65; 95% CI = 0.28, 1.51).

Predictors of Conditions of Delivery among Control Mothers

Among the control mothers, older age and more education increased the likelihood of having a cesarean delivery. Cesarean sections were more frequent among women who were married, who had received some prenatal care, and who were not covered by Medicaid. Women who reported using drugs or who were recorded as having any other medical complication during pregnancy were also more likely to have had a cesarean delivery. Infants delivered by cesarean section were more likely to register a low birthweight. These associations were independent of complications.

Also among the control group, complications at the time of delivery independent of cesarean section were more frequent among low-birthweight and premature infants. None of the other sociomedical variables was associated with risk complications.

Stratified Analysis

Table 3 compares the conditions of delivery between case patients and control subjects by sociomedical factors. Regardless of sociomedical factor, case patients had a lower risk of being delivered by cesarean section without complications and a greater risk of cesarean or vaginal delivery with complications than control subjects, although confidence intervals are wide. Chi-square tests for trends across the delivery categories were statistically significant in most strata. The estimate of the risk of cesarean deliveries with complications among case patients compared with control subjects was highest among those who had received no prenatal care, but because multiple comparisons were made, interpretation of a single finding like this must be cautious.

Among those women in the study reported to have had a previous cesarean section, a cesarean delivery in the index pregnancy was less likely in the case mothers than in the control mothers. This finding was consistent across all sociomedical strata although statistically significant in none.

From the multiple logistic regression model, adjusted for maternal age, education, marital status, prenatal care, drug use, other medical risks during pregnancy, and Medicaid coverage, case patients were less likely than control subjects to have been delivered by cesarean section without complications (OR = 0.77; 95% CI = 0.59, 1.01) and more likely to have had complications at the time of delivery, whether delivered by cesarean section (OR = 1.54; 95% CI = 0.98, 2.43) or vaginally (OR = 1.66; 95% CI = 1.15, 2.39). These are small associations that reach statistical significance only for vaginal deliveries with complications. When birthweight was included in addition to the confounders listed above, cesarean sections without complications remained less likely but became statistically significant (OR = 0.71; 95% CI = 0.54, 0.94); and complications were still more likely in both cesarean section (OR = 1.33; 95% CI = 0.84, 2.12) and vaginal deliveries (OR = 1.32; 95% CI = 0.91, 1.73) among case patients than among control subjects, although associations for complicated deliveries became weaker.

The inclusion of birthweight in the regression model allows for differences between HIV-infected and uninfected

women to be taken into account in characteristics that may be associated with birthweight, such as drug use; it also makes it possible to control for confounding if birthweight is considered an independent risk factor for transmission. However, it is questionable whether birthweight should be controlled in this analysis. If birthweight is either a cause or consequence of the circumstances of delivery or a marker of intrauterine infection, it is within the causal pathway and the model in which it is not included is more appropriate.

Discussion

This study suggests that children with AIDS have a pattern of delivery experiences consistent with the hypothesis that events around the time of delivery that increase the infant's exposure to the birth canal and/or maternal blood influence the risk of maternal-infant HIV transmission. Specifically, there is a deficit of uncomplicated cesarean sections and an excess of complications of delivery in the birth histories of children with AIDS. This pattern persists when sociomedical differences between the AIDS patients and the control group with which they are compared are taken into account.

This study is unique in its attempt to consider not only the fact of cesarean delivery but also the obstetric circumstances of the procedure that may affect the risk of transmission. Cesarean sections provide a proxy measure of exposure to maternal blood during delivery; reasons for undertaking a cesarean section, the status of membranes at the time the procedure is undertaken, and other events occurring during surgery are likely to influence the degree of exposure of the infant to maternal blood and fluids. Our inclusion of other complications at delivery improves on previous measurement of this risk and, albeit somewhat crudely, constructs a biological gradient of intrapartum risk.

However, for this study to be informative about mother-infant HIV transmission, we need to make assumptions about the comparability of HIV-infected and uninfected women. Differences between case patients and control subjects may be owing not to the risk of HIV transmission associated with the different intrapartum factors, but instead to differences between HIV-infected and uninfected women. We should note first that, in our analysis, the HIV status of the control mothers is not directly known whereas all of the case mothers are known to be infected. In New York City as a whole, the prevalence of HIV infection among parturient women was 1.16% in 1991, as measured by unlinked serosurveys of newborn infants (heel sticks) by the New York State Department of Health.[11] The prevalence of infection in the control group studied here may be higher, as these subjects are matched to the case patients by race and institution of birth, and HIV-infected births are unevenly distributed among institutions. For practical purposes, however, most of the control subjects can be assumed to be uninfected.

The decision to deliver an infant by cesarean section is based on a combination of social and medical factors. In this paper, we adjust for many of the social factors shown in the data to be associated with having a cesarean section, including maternal age, education, prenatal care, and health insurance. The assumption that HIV-infected and uninfected women are comparable, conditional on these variables, may be considered valid unless other social factors that make HIV-infected women less likely to have a cesarean delivery can be identified. HIV-infected women may be personally and socially disadvantaged or disorganized in ways not captured by the social variables included here. Also, it is not possible to rule out other possibilities—for example, a reluctance of health professionals to perform cesarean sections on women known or suspected to be HIV infected.

Available data strongly suggest that HIV-infected and uninfected women, conditional on certain social variables, are comparable with respect to their rates of cesarean section. In the New York City Perinatal HIV Transmission Collaborative Study, which recruited parturient women with HIV risk behaviors from New York City hospitals, rates of cesarean section are not different between HIV-infected and uninfected women. Among women reporting injection drug use, 22.4% of seropositive women compared with 23.2% of control mothers had a cesarean section ($\chi^2 = 0.01$, $P = .926$); 19.6% of seropositive and 21.7% of seronegative women who did not report injection drug use had a cesarean section ($\chi^2 = 0.37$, $P = .542$).[12] Similarly, other studies in which these data are available do not show statistically different rates of cesarean section among HIV-infected and uninfected women.[13,14]

Even if we assume that our case and control mothers are not comparable in terms of their rates of cesarean section, we would still need to hypothesize addi-

[a]Vaginal deliveries with no risk complications are defined as the reference group. Subjects in which mode of delivery was missing or defined as "other" are excluded.

tional biases to explain our second finding of an excess of specific complications. None of the sociomedical variables in these data (except birthweight and gestation) was associated with the preselected complications of delivery. Thus, we would have to propose that unidentified disease processes among HIV-infected women increase their risk of complicated deliveries. No statistically significant differences in obstetric complications by serostatus have been reported, although in one study, point estimates of rates of premature rupture of membranes were higher among HIV-positive women (25/80, 31%) than among HIV-negative women (21/109, 19%), but rates of other complications such as placenta previa and abruptio placentae were lower among HIV-positive women (1/85, 1%) than among HIV-negative women (5/118, 4.2%).[15] However, as our estimates suggest modest effects and do not reach statistical significance in every situation, the possibility that our results are owing to small differences between HIV-infected and uninfected women or other unknown biases cannot be definitively ruled out.

From the AIDS case reports, 58% of mothers of children with AIDS are recorded as using injection drugs. It is fairly well established that drug use has an adverse effect on obstetric outcomes,[16] and in the analysis, we control as best we can for maternal drug use during pregnancy. However, this datum may be seriously underreported on the birth certificates, and so adjustment for confounding by drug use may be inadequate. Recording of other medical and risk information on birth certificates may also be incomplete.

Some proportion of infants are likely to be infected before delivery. These cases are uninformative about the risk of intrapartum factors, and were it possible to exclude them, the role of intrapartum factors could be more clearly understood. Reporting of pediatric AIDS in New York City is estimated to be more than 90% complete, but given the relatively recent onset of the epidemic and the long and variable incubation period of AIDS, a cumulative registry tends to favor accrual of cases with short incubation periods. Case patients who could be linked to the birth certificates in this study also appeared to be those diagnosed with AIDS at earlier ages. If the timing of infection affects progression to disease, this series may overrepresent cases attributable to in utero experiences.

If we assume, for the sake of argument, that the results are not due to chance or bias, the measures of effect in this study can be translated into public

health terms. If we assume that the risk of HIV transmission is 25% overall, and use the distribution in the control group to estimate the proportion of specific conditions of delivery while taking the adjusted relative risk estimates from the logistic model, we can calculate the risk of HIV infection under specific conditions of delivery. Under these assumptions, the risk of HIV infection in the group delivered by cesarean section with no complications would be 19%; by cesarean section with complications, 38%; vaginally with complications, 41%; and vaginally with no complications, 25%. Calculating the attributable risk, which is the proportion of cases attributable to the risk factor of interest,[17] 1.6% of cases would be attributable to cesarean sections with complications, 2.6% would be attributable to vaginal deliveries with complications, and 4.6% would be prevented by cesarean sections without complications.

Meta-analysis of several maternal-infant transmission cohorts estimated that 14% of infants delivered by cesarean section are infected compared with 20% of infants delivered vaginally.[18–20] This is a protective effect of a similar order of magnitude to that found in this study for uncomplicated cesarean sections. Further research is needed to clarify the magnitude of the putative protective effect of cesarean sections. Randomized trials would present the strongest design to investigate this as well as to investigate the effect of the procedure on the health of the mother and the child, but such trials may not be ethical or warranted at this time. Further observational evidence is needed that includes data on obstetric circumstances of cesarean sections and potential confounders. As the expected level of protection of an elective cesarean section is modest, the costs and risks associated with the additional surgery may outweigh the potential benefits of the procedure to prevent HIV transmission. Cesarean section is an invasive and expensive intervention[21] associated with small increases in maternal mortality, postoperative and long-term morbidity, and neonatal respiratory problems, all of which are of particular concern in developing countries.[22] Cesarean sections are unlikely to be a successful, widespread means of preventing maternal-infant HIV transmission.

Nevertheless, these findings are consistent with the view that the intrapartum period is a time of risk for HIV transmission. Intrapartum risk has implications for other prevention strategies. The timing of maternal-infant transmission may be important for administration of chemotherapeutic prevention methods, such as nonnucleoside reverse transcriptase inhibitors, other antiretroviral drugs, passive immunization, and, a they become available, other prophylactic medications or vaccines.[23]

As in many other aspects of maternal-child health, prenatal care is critical. Early identification and monitoring of high-risk pregnancies may be beneficial. Unfortunately, many HIV-infected women still do not receive adequate prenatal care. □

Acknowledgments

This study was supported in part by grant 5–P50–MH43520 from the National Institute of Mental Health/National Institute on Drug Abuse.

We would like to thank Dr Mary Ann Chiasson and the New York City Department of Health, Office of Vital Statistics, for collaboration on this project; Dr Shu-Lin Cheng for data abstraction; and Drs Bruce Levin and Ann Gershon for critical review of the study. We would like to acknowledge the work of Sara Back and Diana Sampaio on preliminary aspects of this study.

Substance Use and HIV-Related Sexual Behaviors among US High School Students: Are They Related?

ABSTRACT

Objectives. This study was undertaken to examine whether use of alcohol, cigarettes, marijuana, cocaine, and other illicit drugs is related to the likelihood of sexual behaviors that increase risk for human immunodeficiency virus (HIV) infection among youth.

Methods. The 1990 national Youth Risk Behavior Survey was used to collect self-reported information about a broad range of health risk behaviors from a representative sample of 11 631 high school students in the United States.

Results. Students who reported no substance use were least likely to report having had sexual intercourse, having had four or more sex partners, and not having used a condom at last sexual intercourse. Adjusted for age, sex, and race/ethnicity, odds ratios for each of these sexual risk behaviors were greatest among students who had used marijuana, cocaine, or other illicit drugs. Students who had used only alcohol or cigarettes had smaller but still significant increases in the likelihood of having had sexual intercourse and of having had four or more sex partners.

Conclusions. HIV prevention programs for youth should recognize that substance use may be an important indicator of risk for HIV infection and acquired immunodeficiency syndrome through its association with unsafe sexual behaviors. (*Am J Public Health.* 1994;84:1116–1120)

Introduction

In response to the acquired immunodeficiency syndrome (AIDS) epidemic, the Centers for Disease Control and Prevention (CDC) was given responsibility for assisting relevant national organizations, state and local educational agencies, and other organizations that serve youth to provide effective health education and other interventions to prevent the spread of human immunodeficiency virus (HIV) among youth.[1] Information about the distribution and interrelatedness of behaviors that increase risk for HIV infection among adolescents is important to the success of these programs.[2,3]

Previous studies have found that adolescents who have had sexual intercourse are more likely than those who have not to use alcohol, cigarettes, marijuana, and other illicit substances.[4–8] (Alcohol and tobacco may be considered illicit substances when used by minors.) Research by Kandel and others[9–17] has suggested a progression of substance use among adolescents, beginning with use of at least one category of substances that are legal for adults (i.e., alcohol and/or cigarettes). Alcohol and cigarettes act as "gateway drugs," with use of one or both typically preceding use of marijuana and other illicit drugs. Few adolescents try illicit drugs other than marijuana without prior use of marijuana. Similar stages appear in comparative studies conducted in other Western societies.[11]

There are, however, limitations to the utility of the gateway theory in predicting determinants of initiation of adolescent substance use (e.g., peer drug use, low self-esteem, psychological distress). Attempts to validate particular sets of important factors necessary to progress from one stage to the next have met with some conflicting and contradictory results.[18] For example, Kaplan[19] found that self-derogation (low self-esteem) was an important predictive influence in the marijuana initiation stage, but this was not found by Jessor and Jessor[20] when studying the same transition point.

While the determinants of progressive involvement in substance use may vary, the actual sequence in which substances are initiated remains consistent. A recent study by Kandel confirms that the developmental pattern of drug involvement identified in the 1970s still characterizes adolescent pathways of drug involvement today.[17] This study extends the current literature and refines the association between substance use and sexual behaviors by examining the relationships between typical stages of adolescent substance use and specific HIV-related sexual behaviors—including sexual intercourse, multiple sex partners, and condom use—among a nationally representative sample of high school students.

by the CDC to monitor the prevalence of priority health risk behaviors among youth,[21,22] data about substance use, illicit drug injection, sexual intercourse, and other health risk behaviors were collected in April and May 1990 from a representative sample of US high school students. The 1990 national school-based Youth Risk Behavior Survey used a three stage cluster sample design. The respondent universe consisted of all public and private school students in grades 9 through 12 in the 50 states, the District of Columbia, Puerto Rico, and the Virgin Islands. The first-stage sampling frame included 1921 primary sampling units consisting of large counties or groups of smaller, adjacent counties. Fifty primary sampling units were selected from six strata formed on the basis of urbanization and the percentage of Black or Hispanic students in the unit. The units were selected with probability proportional to school enrollment. In the second stage, 174 schools were selected with probability that was proportional to school enrollment but mathematically biased to increase the chance of selecting schools with a substantial number of Black and Hispanic students. In the final stage, one or two classes of a required subject such as English or social studies were randomly selected within each selected school at each grade 9 through 12. All students in selected classes were eligible to participate in the survey.

A weighting factor was applied to each student record to adjust for nonresponse and the oversampling of Black and Hispanic students. The overall weights were scaled so that the weighted count of students per grade was equal to the number of students for that grade. There were no significant differences in school type (public vs private), urbanicity (metropolitan vs nonmetropolitan area), and size of student enrollment between sampled schools that agreed to participate and those that did not. Characteristics of participating and nonparticipating students could not be compared. To improve comparability to other national data sets and future Youth Risk Behavior Survey sampling frames, the single primary sampling unit and six schools selected from Puerto Rico were excluded from this study. The final weighting factors were adjusted to correct for these deletions.

Survey procedures were designed to protect students' privacy and allow for anonymous participation. Parental consent was obtained prior to survey administration. Trained data collectors administered the questionnaire in the classroom.

Data Analyses

The following sexual risk behaviors were examined: (1) ever having had sexual intercourse; (2) having had sexual intercourse with four or more partners; and (3) not having used condoms at last sexual intercourse.

In addition, students were asked if they had ever used alcohol, cigarettes, marijuana, cocaine, and other illicit drugs such as LSD, PCP, methylenedioxymethamphetamine (MDMA), ecstasy, mushrooms, speed, or heroin. They also were asked if they had ever injected any drug not prescribed by a doctor, such as steroids, cocaine, amphetamines, or heroin.

To examine the relationships between substance use and sexual risk behaviors along the stages of adolescent substance use described by Kandel et al.,[9,14,17] respondents were stratified into one of four mutually exclusive groups based on lifetime use of all five substance categories: (1) students who reported never using alcohol, cigarettes, marijuana, cocaine, or other illicit drugs; (2) students who reported ever using alcohol or cigarettes, but never using marijuana, cocaine, or other illicit drugs; (3) students who reported ever using marijuana, but not cocaine or other illicit drugs; and (4) students who reported ever using cocaine or other illicit drugs. Although route of administration (i.e., injection vs noninjection use of illicit drugs) was not explicitly addressed in Kandel's stages of adolescent substance use, it is logical to assume that adolescents who inject illicit drugs have used an illicit substance other than alcohol, cigarettes, and marijuana. Conversely, adolescents who use illicit drugs such as cocaine, amphetamines, and steroids do not necessarily inject them.

Point estimates and 95% confidence intervals (CIs) were calculated using weighted data and statistical programs that accounted for the complex sample design.[23] Odds ratios (ORs), adjusted for age, sex, and race/ethnicity, were calculated using multiple logistic regression. Differences between point estimates were considered significant if the 95% confidence intervals did not overlap.

Results

The school response rate was 73.8%, and the student response rate was 86.8%. A total of 11 631 questionnaires completed at 124 schools were available for analysis.

Nearly 9 of 10 (88.1%; 95% CI = 86.9%, 89.2%) students reported having had a drink of alcohol at least once during their lifetime, and 72.0% (95% CI = 69.9%, 74.2%) reported having taken at least one or two puffs of a cigarette during their lifetime. Fewer students reported ever having used marijuana (31.4%; 95% CI = 28.6%, 34.1%), cocaine (6.6%; 95% CI = 5.7%, 7.5%), and other illicit drugs (13.1%; 95% CI = 11.4%, 14.9%) such as LSD, PCP, MDMA, ecstasy, mushrooms, speed, or heroin.

Sexual risk behaviors and injection drug use were examined along the progression of adolescent substance use identified by Kandel et al[9,14,17]: (1) 8.9% (95% CI = 7.8%, 9.9%) of students reported never having used any substance; (2) 57.9% (95% CI = 55.3%, 60.4%) had used only alcohol or cigarettes; (3) 18.8% (95% CI = 16.7%, 20.9%) had used marijuana, but not cocaine or other illicit drugs; and (4) 14.5% (95% CI = 12.6%, 16.3%) had used, but not necessarily injected, cocaine or other illicit drugs. More than half (54.2%) the students reported ever having had sexual intercourse, and 19.1% reported having had sexual intercourse with four or more partners during their lifetime (Table 1). Among students who reported ever having sexual intercourse, 53.6% did not use a condom the last time they had sexual intercourse. The prevalence of sexual risk behaviors was least among students who reported no substance use; increased among students who used alcohol or cigarettes; and was greatest among students who used marijuana, cocaine, or other illicit drugs. Approximately 1 of 11 (8.9%) students who used cocaine or other illicit drugs reported injection drug use (Table 1).

In addition to potential involvement in injection drug use, students who used cocaine or other illicit drugs were most likely to report the riskiest combination of sexual behaviors. That is, nearly one third (30.2%) of these students have had sexual intercourse with four or more partners and did not use a condom the last time they had sexual intercourse (Table 2).

Previous analyses of these data have presented the prevalence of substance use and sexual risk behaviors separately by demographic characteristics.[24–27] In this analysis, adjusted odds ratios were calculated to measure the association between lifetime substance use and sexual risk behaviors, controlling for age, sex, and

[c]Reported ever using marijuana, but never using cocaine or other illicit drugs.
[d]Reported ever using cocaine or other illicit drugs such as LSD, PCP, MDMA, ecstasy, mushrooms, speed, or heroin.

race/ethnicity. Compared with students who reported no substance use, those who used marijuana, cocaine, or other illicit drugs were more likely to report ever having had sexual intercourse, having had four or more sex partners, and not having used a condom at last sexual intercourse. Students who used only alcohol or cigarettes had smaller but still significant increases in the likelihood of ever having had sexual intercourse and having had four or more sex partners, but they were not different from those who reported no substance use in their use of condoms at last sexual intercourse (Table 3).

Discussion

As with other school-based surveys, our findings are likely to underestimate substance use, injection drug use, and sexual risk behaviors among the entire adolescent population since illicit drug use and early sexual intercourse are associated with school dropouts.[8,28–32] Nevertheless, these data suggest that sexual behaviors place a sizable proportion of high school students at risk for HIV infection. More than half of all high school students have already engaged in sexual intercourse, and less than half of those who are sexually active used a condom the last time they had sexual intercourse. Further, the likelihood of these sexual risk behaviors increases as substance use progresses from alcohol and cigarettes to marijuana, cocaine, and other illicit drugs. Approximately one of nine high school students reported both having had four or more sex partners during their lifetime and not having used a condom at last sexual intercourse. Among students who had used cocaine or other illicit drugs, nearly one third reported this combination of sexual risk behaviors. It should be noted that the

percentage of students who have ever had sexual intercourse represents an upper bound on the proportion at risk for HIV infection and AIDS due to sexual behaviors, given that some individuals who have sexual intercourse always use a condom, and some individuals who have sexual intercourse without a condom may be involved in a long-term monogamous relationship with an uninfected partner.

The strong association found in this study between cocaine use and sexual behaviors that increase risk for HIV infection has been noted by others. Several recent studies have examined the sexual behaviors of inner-city, mostly minority youth who use crack,[33–37] an inexpensive and smokable form of cocaine that is highly addictive. Its use by adolescents and young adults has been associated with high-risk sexual behaviors (e.g., exchanging sex for crack or money to buy crack) and HIV infection. Nearly 50% of HIV-infected adolescents seen at an outpatient clinic in New York City reported heavy crack use.[35]

A small proportion of students place themselves at risk for HIV infection through injection drug use. Still, our study suggests that nearly 190 000 (1.5%) of the approximately 12.5 million[38] high school students in the United States have injected cocaine or other illicit drugs. This estimate represents an upper bound on the number of high school students at risk for AIDS due to injection drug use, given that not all injection drug users share needles.

Our study is cross-sectional in design and cannot provide evidence of a causal relationship between substance use and sexual behaviors. Nevertheless, the positive association between stages of adolescent substance use and sexual behaviors that increase risk for HIV infection has important implications. HIV prevention programs for youth should recognize that progressive involvement in substance use may be an important indicator of risk for HIV infection and AIDS, not only through injection drug use but also, and perhaps more importantly, through its association with unsafe sexual behaviors. The association between early stages of substance use and sexual risk behaviors suggests that HIV prevention programs for youth should discourage all substance use. Although cocaine and other illicit drugs were associated with both injection drug use and the greatest likelihood of sexual risk behaviors, use of alcohol and cigarettes were associated with sexual risk behaviors also, albeit to a lesser degree. Further, it is rare for an adolescent to use cocaine or other illicit drugs without first using alcohol, cigarettes, and marijuana.[9,14,17]

TABLE 3—Adjusted Odds Ratios (ORs)[a] and Confidence Intervals (CIs) for Sexual Risk Behaviors, by Lifetime Pattern of Substance Use: Youth Risk Behavior Survey, 1990

Lifetime Pattern of Substance Use	Ever Had Sexual Intercourse		Had Sexual Intercourse with ≥4 Partners		Did Not Use Condom at Last Sexual Intercourse[b]	
	OR	95% CI	OR	95% CI	OR	95% CI

Alcohol/cigarettes[d]	4.0	3.0, 5.4	2.7	1.7, 4.2	1.2	0.8, 1.8
Marijuana[e]	17.4	12.9, 23.5	9.2	5.7, 14.9	1.7	1.1, 2.5
Cocaine/other[f]	31.4	22.3, 44.2	26.8	17.3, 41.4	2.3	1.5, 3.7

[a]Adjusted for age, sex, and race/ethnicity.
[b]Among students who reported ever having had sexual intercourse.
[c]Reported never using alcohol, cigarettes, marijuana, cocaine, or other illicit drugs.
[d]Reported ever using alcohol or cigarettes, but never using marijuana, cocaine, or other illicit drugs.
[e]Reported ever using marijuana, but never using cocaine or other illicit drugs.
[f]Reported ever using cocaine or other illicit drugs such as LSD, PCP, MDMA, ecstasy, mushrooms, speed, or heroin.

Another implication of our study involves substance abuse treatment programs that serve youth. Our findings suggest that adolescents who use substances, especially cocaine and other illicit drugs, should receive appropriate counseling and other interventions to reduce sexual behaviors that increase their risk for HIV infection.

National health objectives for the year 2000 seek to increase school-based education to prevent HIV infection (objective 18.10), alcohol and other drug use (objective 4.13), and tobacco use (objective 3.10), preferably as part of quality school health education.[39] There is empirical evidence that well-planned prevention curricula based on social science principles can have a favorable impact on tobacco, alcohol, and other drug use[40] as well as on AIDS-related knowledge, beliefs, self-efficacy, and behaviors among high school students.[41] Substantial and long-lasting reductions in substance use and sexual risk behaviors may require comprehensive, multicomponent interventions that integrate theory-based skill-building education programs for youth with individual counseling, parental involvement and training, and community involvement to ensure access to needed social and health services.[32,42–45] Schools can help by providing developmentally appropriate HIV prevention education within the context of planned and sequential, kindergarten through 12th grade, comprehensive school health education programs that integrate and coordinate efforts to prevent substance use, HIV infection, sexually transmitted diseases, unintended pregnancies, and other important health problems.[46] □

Longitudinal Tracking of Adolescent Smoking, Physical Activity, and Food Choice Behaviors

ABSTRACT

Objectives. A major assumption underlying youth health promotion has been that physiological risk factors track from childhood into adulthood. However, few studies have systematically examined how behaviors change during adolescence. This paper describes longitudinal tracking of adolescent health behaviors in two Minnesota Heart Health Program communities.

Methods. Beginning in sixth grade (1983), seven annual waves of behavioral measurements were taken from both communities (baseline n = 2376). Self-reported data included smoking behavior, physical activity, and food preferences.

Results. A progressive increase in the change to weekly smoking status was observed across the smoking status categories. As students began to experiment with smoking, they were more likely to either begin to be or remain regular smokers. Tracking of physical activity and food choice variables was also apparent. In nearly all the follow-up periods, the students identified at baseline as measuring high remained high, and those measuring low remained low.

Conclusions. These results indicate that there is evidence of early consolidation and tracking of physical activity, food preference, and smoking behavior. The early consolidation of health behaviors implies that interventions should begin prior to sixth grade, before behavioral patterns are resistant to change. The smoking results suggest that students are experiencing difficulty quitting smoking; thus, youth smoking cessation interventions are warranted. (*Am J Public Health.* 1994;84:1121–1126)

Introduction

Efforts directed toward the primary prevention of cardiovascular disease in youth populations have typically focused on the modification of health behaviors such as physical activity, dietary intake, and cigarette smoking. The major assumptions for the rationale behind youth health promotion have been that (1) a certain proportion of children and adolescents are at excess physiological and behavioral risk; (2) physiological risk factors track from childhood into adulthood; (3) the development of physiological risk factors depends largely on the initiation of health-compromising behaviors (such as poor eating and physical activity habits, and cigarette smoking); and (4) primary prevention can be achieved through the modification of behaviors known to be related to physiological risk factors before behavioral patterns are more fully established and resistant to change.[1,2]

Many studies have provided evidence substantiating these assumptions. The relationship between dietary intake, physical activity, cigarette smoking, and cardiovascular disease for adults is well known.[3,4] There is early physiological evidence of cardiovascular disease where fatty streaks and atheromatous changes have been found in the aortas and coronary vessels of children and young adults dying of unrelated disease and war injuries.[5,6] During the past decade there have been six major studies tracking physiological risk factors for cardiovascular disease in childhood, and these studies have each indicated that total, low-density, and high-density lipoprotein cholesterol measurements in childhood and adolescence are predictive of adult values.[7–13] The onset of smoking begins with initial favorable attitudes toward smoking, and as youth move through middle and high school, a substantial proportion progress from initiation to occasional smoking and on to regular nicotine-dependent smoking.[14,15] Few individuals initiate smoking past high school.[16] Finally, several primary prevention studies have investigated various youth health promotion strategies and found encouraging results.[17]

Few studies have systematically examined how cardiovascular disease–related behaviors change during childhood and adolescence within a cohort of youth. If youth health behaviors track during childhood and adolescence, it would add support to the primary assumptions given for early interventions to prevent cardiovascular disease. For this paper, tracking is defined as the stability of health behaviors over time, or the maintenance of relative position in rank of behavior over time.

Methods

Research Design

The Class of 1989 Study annually measured a cohort of students from 6th to

Note. Each cell represents that column's percentage of change to weekly smoker over a 1-year interval. For example, 13.5% of experimental smokers in the reference community became weekly smokers between sixth and seventh grades.

12th grade on a variety of health behaviors. The study was designed to test the efficacy of a school-based cardiovascular disease prevention program embedded in the Minnesota Heart Health Program community campaign to reduce heart disease.[1,18] The research design, interventions, and main outcomes of the study have been described elsewhere.[1,18–22]

Two of the six communities in the Minnesota program were involved in the Class of 1989 Study. All sixth graders enrolled in the public schools in both communities were invited to participate in a baseline survey in April 1983, and that grade cohort was surveyed annually in April until their graduation from high school in 1989. The students in the intervention community participated in 5 years of Minnesota Heart Health Program–sponsored behavioral health programs in school from 6th through 10th grade and also were exposed to the Minnesota program community interventions. The intervention results indicate positive community and school intervention effects on youth smoking, physical activity, and food choice behaviors.

Outcome Evaluation

The measures for cigarette smoking each year included standardized self-reported items.[19,23] Two variables were used: weekly smoking prevalence and a multilevel categorical variable of never smoker, experimental smoker, quitter, and weekly smoker. The measures for physical activity each year were self-reported hours of exercise per week and a physical activity score.[20,24] For these analyses, hours of exercise per week was also divided into four categories: less than 1 hour, 2 to 3 hours, 4 to 5 hours, and greater than 6 hours per week. In the physical activity score, which measured frequency and intensity of regular physical activity, each unit increase means greater frequency and intensity of physical activity. For these analyses, the physical activity score was also divided into tertiles. The measure for dietary intake was self-reported food preferences.[21,24] Students were asked to select from 18 food pairs the "one food they would usually eat when they had the choice"; a unit increase means one more healthier food choice. For these analyses, the food choice score was divided into quintiles.

Analysis Methods

The tracking analyses were accomplished for the physical activity and food choice variables by dividing baseline values into categories (quintiles or tertiles) and computing the subsequent mean values for students originally within those categories. If a mean value within any sixth-grade category maintained a relative position in rank compared with that in the other categories, this was interpreted as evidence of tracking. Using PROC GLM in SAS,[25] a model was fit for each year of follow-up (7th to 12th grades) on the three behavioral physical activity and food choice dependent variables. These analyses were stratified by sex and intervention community, and were adjusted for age, sex, and, in the later years of measurement, school and parental occupation (1986 to 1989 for school; 1987 to 1989 for parental occupation).

This type of tracking analysis is meant to be descriptive; evidence of tracking should be observed by plotting the mean values within sixth-grade categories across time. An additional analysis was performed to determine any differential trends within those categories across time. Using PROC GLM repeated measures in SAS,[25] a model was fit that included a sixth-grade category by time interaction. This analysis approach was used to determine the mean change within categories from 7th to 11th grade on the dependent variable. In this case, a nonsignificant result indicates an equal amount of change within each category and would support the tracking hypothesis. Eleventh grade was selected to assess the change over time in preference to 12th grade because of extensive attrition in 12th grade, particularly in the reference community.

A different analytic approach was taken to assess tracking of cigarette smoking behavior. Because few students are smoking in 6th grade and rapid yearly onset is expected up to 10th grade, the change in smoking status from one year to the next was examined. Using the four-level smoking status variable, the change over a year to weekly smoking from each of the four smoking categories—that is, the proportion of students changing from never smoker, experimental smoker, or quitter to weekly smoker; and those students remaining a weekly smoker (over the year)—was calculated. Again, these analyses were meant to be descriptive, and no statistical testing strategy was used.

Results

Tracking of Smoking Behavior

Table 1 presents data for the adjusted change to weekly smoking from year to year within each of the four smoking categories for both the reference and intervention communities. Significant intervention effects have been reported elsewhere, so these results have been stratified by intervention condition.[19] In

the reference community, the shift from never to weekly smoker from sixth to seventh grade was 3.3%; from seventh to eighth grade, 4.1% of never smokers became weekly smokers, and so on. Likewise, the shift from sixth to seventh grade from experimental smoker to weekly smoker was 13.5%.

A consistent pattern in the change to weekly smoking status can be seen in Table 1 across the smoking status categories. These data indicate a stable and consistent multistage pattern of onset, in which fewer students move from never to weekly smoking than move from never smoking to experimenting, quitting, or remaining weekly smokers. The results are striking for the column of weekly smokers remaining weekly smokers, which indicates that students who smoke are increasingly unlikely to quit as they get older. This observation is corroborated by the quitter column, in which a large proportion of students return to weekly smoking after reporting having quit smoking.

Noticeable differences were observed between the reference and intervention communities, particularly from sixth to seventh and from seventh to eighth grades, where the school smoking intervention occurred. In both of these rows, the change to weekly smoking was lower in the intervention community. In addition, nearly all the cells on the intervention half of the table have a lower weekly smoking prevalence compared with the reference half, some by 10% or more.

FIGURE 1—Tracking of healthy food choices: females.

Tracking of Healthy Food Choices

Figure 1 presents tracking of healthy food choices for females by reference and intervention communities. Significant intervention effects by sex have been reported elsewhere, so results have been stratified by intervention condition and sex.[21] The mean number of healthy food choices was calculated and plotted from 7th to 12th grade within the 6th-grade categories of students. If food choices track, the cohort of 6th-graders' values would be expected to remain separate and distinct over time; if the behavior does not track, the lines would be expected to cross and overlap over time. The bottom portion of Figure 1 includes data on differential trend; this refers to the mean change from 7th to 11th grade within the 6th-grade categories. A nonsignificant test for differential trend is interpreted as no difference in the repeated measures change by 6th-grade category from 7th to 11th grade. Thus, a nonsignificant result supports the tracking hypothesis; a significant differential trend would indicate that at least one category has changed compared with the others over time.

In 6th grade, the healthy food choice variable was divided into quintiles, and the mean number of choices was calculated within those quintiles and plotted from 7th to 12th grade. In Figure 1, a noticeable parallel separation between the groups was observed that visually supports behavioral tracking; that is, sixth-grade rankings of healthy food choices are likely to maintain over time. In sixth grade, at all follow-up periods, those in quintile 1 were significantly different from quintile 5, quintiles 1 and 3 were significantly different at 10 of 12 follow-up periods, and quintiles 3 and 5 were significantly different at 11 of 12 follow-up periods. Additional corroborating evidence is offered by the nonsignificant tests for differential trend in the reference community. A significant differential trend was observed in the intervention community as the increase in the lower two quintiles surpassed that of the upper three, a finding not unexpected since significant intervention effects were observed (reported elsewhere).[21] Similar results were observed for males in that all 12 comparisons between quintiles 1 and 5 and between quintiles 3 and 5 were significant, as were 11 of 12 comparisons between quintiles 1 and 3. Both differential tests for trend were nonsignificant.

Tracking of Activity Score and Hours of Exercise per Week

Figure 2 presents tracking of the activity score (frequency and intensity of physical activity) for sixth-grade females by reference and intervention communities. In these figures, the activity score was divided into tertiles, where tertile 1 represents the least physically active third of the distribution.

A clearly defined pattern of tracking can be observed across the grades. With the exception of one follow-up period, tertile 1 was significantly different from tertile 3. Both tests for differential trend were nonsignificant, corroborating the visual tracking result. The intervention effects of the Class of 1989 Study are also discernible in Figure 2, where the lowest tertile for females appears to have been influenced to a greater extent than tertile 3. This pattern was not unexpected because there were significant intervention effects (reported elsewhere).[21] Similar results were observed for males in that 10 of 12 comparisons between tertiles 1 and 3 were significant, and a significant differential test for trend was observed in the intervention community.

Figure 3 presents tracking of hours of exercise per week for females by reference and intervention communities. Significant intervention effects by sex have been reported elsewhere, so results have

been stratified by intervention condition and sex.[20] Here again, a clear pattern of tracking can be observed. This observation is most apparent when comparing the highest (6+) with the lowest (<1) groups of exercisers; at each follow-up period, these groups were significantly different. This finding is corroborated by the nonsignificant test for trend in both communities. Similar results were observed for males in that all 12 comparisons between high and low groups were significant, and a significant differential test for trend was observed in the intervention community.

Attrition Analysis

Financial constraints precluded any attempt to contact those students who were not present in class the day of the survey. Response rates for the entire sample for the six follow-up periods were 88%, 81%, 70%, 66%, 59%, and 45% (n's at baseline: intervention = 1342; reference = 1034). These response rates were approximately equal by community with the exception of the last year of data collection, when 55% of the intervention community students were resurveyed compared with 31% of the reference community. Students who were not measured at one survey typically displayed mean values on prior surveys that were less healthy than those of students who were present at more measurement periods.[19-21] Differential attrition bias has been explored and response rates within these categories were nearly equivalent, indicating little if any attrition bias.

Discussion

The concept of behavioral tracking refers to the maintenance of relative ranking of students over time on a given health behavior. These results support the hypothesis that the cardiovascular disease–related behaviors measured in the Class of 1989 Study tracked from 6th to 12th grade. A progressive increase in the change to weekly smoking status was observed across the smoking status categories. A stable and consistent multistage pattern of smoking onset was observed in which fewer students moved to weekly smoking from never smoking than moved from experimenting, quitting, or remaining weekly smokers. Figures 1 through 3, which show the tracking data for the physical activity and food choice variables, all offer visual evidence of tracking. In nearly all the follow-up periods, the students identified in sixth grade as measuring high on any variable remained high, and those measuring low remained low.

These data indicate a clear pattern of tracking and may be interpreted as support for one of the assumptions underlying the rationale for youth health promotion. If students separate at an early age into high- and low-risk groups and maintain their relative ranking over time, presumably into adulthood, then interventions to alter the risk at or before the age of separation are warranted. In addition, these results, coupled with results previously published from these data that indicate a significant amount of covariation among these behaviors,[26] provide evidence that early intervention across multiple risk behaviors is appropriate.

The tracking information not only provides justification for interventions targeting adolescents and younger children, but also may be of assistance to improve the content of future health promotion interventions. A striking pattern of data observed for smoking tracking suggests that once students become weekly smokers, they are unlikely to give up cigarettes. Of the students who were current smokers, an increasing percentage remained smokers over the years of follow-up; they were either unable or unwilling to quit smoking. Of the self-reported quitters, 13% to 46% returned to weekly smoking by the next year's measurement period. Both these observations suggest that nicotine addiction begins early in the students' use of tobacco. From an intervention perspective, these data clearly warrant continued smoking

prevention efforts as well as smoking cessation interventions among high school–aged students. Yet research on the effectiveness of smoking cessation interventions in this age group has not been extensive or encouraging.[27] On the other hand, for the students who self-report having made the effort to quit smoking, 64% to 87% were able to remain a nonsmoker over a year, a rate higher than that reported in most professionally led adult smoking cessation interventions.[28] These higher than expected rates of quitting may be owing to classification error where we cannot be certain of the students' level of involvement with tobacco prior to quitting. Nevertheless, if students who make the effort to quit smoking are relatively successful, encouraging greater numbers of teenage smokers to contemplate or self-initiate quitting may be a useful strategy in combination with smoking prevention programs.

The tracking data for physical activity and healthy food choices offer convincing evidence in support of tracking from 6th to 12th grade. The upward or downward trends across the variables indicate that students are indeed changing their behaviors over time but that the change is relative to the behavior of their peers. This persistence in rankings suggests that consolidation of these health behaviors may begin prior to sixth grade and that interventions in early grade school are warranted. The observation that groups maintain relative ranking indicates that there are subgroups of students who remain at higher risk than their peers. These higher risk groups may require additional intervention to improve their risk profile. Interestingly, the significant tests for differential trend in the intervention community were largely owing to positive changes among those at highest risk. This suggests that the intervention program appears to have had a larger effect among those who needed it most.

Although data from the Class of 1989 Study provide information about patterns of tracking, the limitations must be considered. One possible source of bias for interpretation of the eating and physical activity–related tracking results pertains to measurement. First, the measurement instruments were designed to detect intervention impact and are appropriate for determining differences in group means, but they do not reflect actual nutritional intake and may not accurately reflect true levels of physical activity. There are many difficulties inherent in measuring nutrition and physical activity levels, especially in youth populations.[29] For example, it is clear that healthy food choices are tracking over time, but it is unclear how much these variables relate to actual fat, salt, and carbohydrate consumption. Self-reported measures are subject to demand characteristics such as social desirability or repeated testing that introduces additional within- or between-person variation. The additional variation caused by measurement error, however, would reduce the chances of detecting tracking. Second, self-reported smoking data were not verified with objective biochemical measurements, and these data do not include students who have dropped out of school, a group known to have high rates of smoking.[30] Thus, the smoking rates presented probably underestimate smoking prevalence among adolescents.

The results from the Class of 1989 tracking analysis indicate that there is evidence of early consolidation and tracking of physical activity, food choice, and smoking behaviors. The results have implications for the assumptions underlying school health promotion. First, the early consolidation of health behaviors implies that interventions should begin prior to sixth grade, before the behavioral patterns become more difficult to change. If the tracking of health behaviors is found to be a general phenomenon, it is possible that interventions designed for younger students may move the entire student distribution toward healthier behavioral practices and further improve the impact of interventions at later grades. Future research should replicate these results, beginning with a younger sample of students.

Second, the smoking results indicate that smoking students are addicted to tobacco and are in need of smoking cessation interventions. This appears to be a fertile area of investigation as very few studies have been published on youth smoking cessation programs. In addition, smoking cessation may be facilitated by inserting cessation messages into existing smoking prevention programs, especially in 9th and 10th grades, when the prevalence of smoking warrants greater cessation efforts. □

Planning the 1997 National Health and Nutrition Examination Survey

The National Center for Health Statistics, Centers for Disease Control and Prevention, is soliciting suggestions for topics to be considered in the planning process for the next National Health and Nutrition Examination Survey (NHANES), scheduled for 1997. As in previous NHANES, the primary purpose will be to measure and monitor the health and nutritional status of the US population.

Please send all research suggestions by *October 1, 1994.* Submit specific recommendations, including brief descriptions of the suggestion's public health importance and the available data collection methodologies, to Vicki Burt, Chief, Survey Planning and Development Branch, Division of Health Examination Statistics, National Center for Health Statistics, Presidential Building, Rm 1000, 6525 Belcrest Rd, Hyattsville, MD 20782.

Low Birthweight at Term and the Timing of Fetal Exposure to Maternal Smoking

Ellice Lieberman, MD, DrPH, Isabelle Gremy, MD, MPH, Janet M. Lang, PhD, ScD, and Amy P. Cohen, BA

ABSTRACT

Objectives. This study was undertaken to evaluate the risk of small-for-gestational-age birth for women who stop smoking or begin to smoke during pregnancy.

Methods. Women with term singleton pregnancies from a hospital-based cohort of 11 177 were classified as (1) nonsmokers; (2) smoked throughout pregnancy; (3) smoked during first trimester only; (4) smoked during first and second trimesters only; and (5) smoked during second and third trimesters or during third trimester only. Risk of small-for-gestational-age birth according to smoking category was estimated and adjusted for confounding factors by logistic regression.

Results. Women who stopped smoking by the third trimester were not at increased risk of small-for-gestational-age birth compared with nonsmokers. Women who began smoking during the second or third trimester had an elevated risk of small-for-gestational-age birth (odds ratio [OR] = 1.83; 95% confidence interval [CI] = 1.25, 2.67) similar to that for women who smoked throughout pregnancy (OR = 2.20; 95% CI = 1.90, 2.54). Risk of small-for-gestational-age birth increased with the number of cigarettes smoked during the third trimester.

Conclusions. It is during the third trimester that smoking retards fetal growth, presenting a compelling opportunity for smoking cessation interventions. Programs must emphasize the importance of not resuming smoking late in pregnancy. (*Am J Public Health.* 1994;84:1127–1131)

Introduction

Women who stop smoking during pregnancy give birth to heavier infants than those who continue to smoke throughout pregnancy.[1–6] However, the few studies investigating the effect of the timing of smoking cessation have not yielded consistent results. Rush and Cassano,[2] as well as Hebel et al.,[5] found that stopping smoking during pregnancy at any time up through the eighth month nullified the negative effect of smoking on birthweight but that stopping in the ninth month did not. In contrast, MacArthur and Knox concluded that women needed to stop by 16 weeks to nullify the effect of smoking, and that stopping between 16 and 30 weeks only moderated the effect on birthweight.[3]

Additionally, most studies report their findings as birthweight differences between nonsmokers, persistent smokers, and quitters[2,3,5] without distinguishing whether those differences resulted from short gestation or impaired fetal growth. As low birthweight in infants of smokers results largely from impaired fetal growth, a more direct measure of effect is the proportion of infants born small for their gestational age.[7] Such infants are known to be at increased risk of fetal mortality as well as of neonatal morbidity and mortality[8–10] (although their risk is not as great as that of infants who are very premature).

How the timing of smoking cessation during pregnancy influences the occurrence of small-for-gestational-age births has important public health implications for the planning of smoking cessation interventions for women of childbearing age. Additionally, it is important to examine the effects for women who begin smoking during pregnancy. This study examines the effect of changes in smoking habits during pregnancy on the occurrence of term undersized births.

Methods

The Delivery Interview Program, conducted at the Boston Hospital for Women from August 1977 to March 1980, was designed to study the association between late pregnancy outcome and a wide variety of exposures. Data collected from interviews and medical record reviews included medical and obstetric history, course of the current pregnancy, and infant outcome, as well as demographic information. Women were also asked about their smoking habits, including the number of cigarettes smoked per day during each trimester of pregnancy. A total of 12 718 women were interviewed and had their medical records reviewed. Further details of the study methodology have been presented elsewhere.[11]

For this analysis, the cohort was limited to the 11 177 women who gave birth to term, liveborn infants of known sex and on whom complete smoking information was available. Only term

pregnancies (37 or more weeks gestation) were investigated so as to assess the specific effects of smoking on the occurrence of growth retardation rather than of low birthweight. There were not sufficient numbers of preterm infants who were growth retarded to examine the effect of smoking on intrauterine growth in that population. Term infants were categorized as being small for gestational age if their birthweight was less than the 10th percentile for their gestational age and sex using the criteria established by Williams et al.[12] For gestational age, the obstetrician's best estimate at the time of birth, which was available for all women, was used instead of last menstrual period, which was missing for 10% of subjects and was more often missing for women of low socioeconomic status. The two methods were in good agreement, differing by less than 2 weeks for 95% of births.

Women were categorized into one of five groups, according to their smoking habits:

1. Nonsmokers: women who never smoked and those who stopped smoking prior to pregnancy were combined, as both our analyses and the literature indicate no residual effect of smoking prior to pregnancy on infant birthweight[2]
2. Smoked throughout pregnancy
3. Smoked during the first trimester of pregnancy only
4. Smoked during the first and second trimesters of pregnancy only
5. Smoked during the second and third trimesters or during the third trimester only. These women began smoking during either the second trimester (n = 158) or the third trimester (n = 70) and continued to smoke for the remainder of pregnancy. These could represent women who stopped smoking prior to pregnancy and relapsed prior to delivery. Groups starting at different times were combined because of small numbers.

The crude risk of small-for-gestational-age birth according to smoking category was determined. Logistic regression analysis was used to determine the risk for each smoking category while controlling for the following potential confounding factors: maternal education, race, age, marital status, payment source, height, body mass index, pregnancy weight gain, parity, late prenatal care, and medical conditions (pre-eclampsia, urinary tract infection, and history of in utero diethylstilbestrol [DES] exposure). The logistic regression model contained four indicator variables for smoking status (a separate variable for each category of smokers), with nonsmokers as the referent group; the relative risk of small-for-gestational-age birth was determined for each smoking category relative to the nonsmoking group. In all logistic regression analyses, odds ratios (ORs) calculated from regression coefficients were used as estimates of relative risk. Confidence intervals (CIs) were calculated from the standard errors of those coefficients.

Risk of small-for-gestational-age birth could be influenced not only by changes in smoking habits but also by the number of cigarettes smoked. To investigate this, logistic regression was used to estimate the association of such a birth with smoking cessation independently for the two subgroups of smokers for whom there were adequate numbers: light smokers (up to 10 cigarettes per day; n = 1613)

and moderate smokers (11 to 20 cigarettes per day; n = 1098). Those women smoking more than 20 cigarettes per day (n = 428) and those who began smoking during pregnancy (n = 228) were not evaluated because of small numbers. Women were categorized according to first trimester smoking habits, as this was the only time when all the women being evaluated smoked.

In addition to evaluating the occurrence of small-for-gestational-age births, a dichotomous outcome, this study also used multiple linear regression (with birthweight as the dependent variable) to investigate the effect of changes in smoking habits on mean birthweight among term infants. In addition to the confounders noted above, gestational age and infant sex were included in these regression models, as infants of 40 weeks' gestational age are somewhat heavier than 37-week infants and male infants are heavier than female infants. Predicted differences in birthweight and the 95% confidence intervals relative to the nonsmoking group were calculated.

Results

There were 11 177 women with term singleton births included in the current analysis. Within the study population, 1188 (10.6%) women gave birth to small-for-gestational-age infants. Women giving birth to such infants differed in various ways from women whose infants were of appropriate size (Table 1). They were more likely to be Black, on welfare, single, less educated, less than 20 years of age, and primiparous; to begin prenatal care later in pregnancy; and to have medical conditions. Additionally, mothers of undersized infants tended to be shorter and thinner (low body mass index), and to gain less weight during pregnancy. These potential confounders were entered into the multivariate model.

Thirty percent (n = 3367) of the women in this cohort smoked at some time during pregnancy (Table 2). Of the smokers, 2449 (73%) smoked throughout pregnancy, 690 (20%) smoked early in pregnancy but quit, and 228 (7%) did not smoke during the first trimester but began to smoke during the second or third trimester and continued through the end of pregnancy. The frequency of small-for-gestational-age births differed according to smoking category (Table 2). Women who smoked throughout pregnancy were at about twice the risk of giving birth to undersized infants than were nonsmokers (17.7% vs 8.5%). For women who smoked only during the first trimester or during the first and second trimesters and then stopped, the risk was similar to that for nonsmokers (8.7% and 7.2%, respectively, vs 8.5%), while women who began smoking during the second or third trimester of their pregnancy had a rate of small-for-gestational-age birth close to that for women who smoked throughout pregnancy (15.4% vs 17.7%).

These associations did not change in logistic regression analyses that controlled for the potential confounding factors described earlier. The risk of giving birth to an undersized infant for women who smoked during either the first trimester only (OR = 1.04; 95% CI = 0.76, 1.43) or the first and second trimesters (OR = 0.83; 95% CI = 0.43, 1.61) was similar to that for nonsmokers. Women who began smoking during the second or third trimester were at increased risk of such an outcome (OR = 1.83; 95% CI = 1.25, 2.67), as were those who smoked throughout pregnancy (OR = 2.20; 95% CI = 1.90, 2.54). As maternal weight gain could mediate the effect of smoking on fetal growth, an additional analysis was performed without this factor; our results were virtually unchanged.

Women who smoked throughout pregnancy also smoked, on average, more cigarettes per day than those who stopped smoking (Table 2). To disentangle the effects of duration from the effects of quantity, logistic regression analyses were performed (controlling for confounders above) to determine the association of changes in smoking habits and risk of small-for-gestational-age birth separately for light and moderate smokers. Light smokers were those who smoked up to 10 cigarettes per day in the first trimester whereas moderate smokers were those

TABLE 2—Frequency at Term of Small-for-Gestational-Age Births, According to Smoking by Trimester

Smoking by Trimester	No. of Women	Frequency of Small-for-Gestational-Age Births, %	Mean No. of Cigarettes/day
Nonsmoker	7810	8.5	0
Smoked throughout	2449	17.7	15.3[a]
Smoked first trimester only	552	8.7	10.8[a]
Smoked first and second trimesters only	138	7.2	13.5[a]
Smoked second and third or third trimester only	228	15.4	7.7[b]
Total	11 177	10.6	

[a]For comparability, estimates for these groups are based on the number of cigarettes/day smoked during the first timester.
[b]Estimates are based on the number of cigarettes/day smoked during the third trimester, since women in this group did not smoke during the first timester.

TABLE 3—The Risk of Small-for-Gestational-Age Birth at Term for Light and Moderate Smokers, According to Maternal Smoking by Trimester[a]

Infant's Exposure to Smoking, by Trimester	Light Smokers[b] (n = 1613) Odd Ratio	Light Smokers[b] (n = 1613) 95% Confidence Interval	Moderate Smokers[c] (n = 1098) Odd Ratio	Moderate Smokers[c] (n = 1098) 95% Confidence Interval

TABLE 4—Adjusted Odds Ratio (AORs) and 95% Confidence Intervals (CIs) of Small-for-Gestational-Age (SGA) Birth at Term, According to Number of Cigarettes Smoked during the Third Trimester

Cigarettes/ Day	No. of Women	Percentage of SGA Births	AOR (95% CI)[a]
0	7810	8.5	1.0 (referent group)
1–5	685	14.7	1.69 (1.33, 2.14)
6–10	649	18.0	2.16 (1.72, 2.72)
>10	1343	18.7	2.48 (2.08, 2.95)

[a]From a multiple logistic regression model controlled for education, race, payment source (insured, welfare, other), age, marital status, body mass index, height, weight gain, late prenatal care, parity, exposure to diethylstilbestrol (DES), hypertension, urinary tract infection.

who smoked 11 to 20 cigarettes per day in the first trimester. For both groups, the effect of smoking throughout pregnancy and of smoking cessation were similar to that for the overall cohort. Light smokers had an odds ratio of 1.78 (95% CI = 1.44, 2.20) for the occurrence of undersized birth whereas the odds ratio for moderate smokers was 2.55 (95% CI = 2.10, 3.09). For both groups, women who stopped smoking did not have a significantly increased risk of small-for-gestational-age birth when compared with nonsmokers (Table 3). These data indicate that the effect observed in the overall cohort was not solely owing to the fact that women who stopped smoking were initially lighter smokers. Additionally, while women who started smoking during the second or third trimester smoked fewer cigarettes on average than women who smoked throughout pregnancy, their risk of small-for-gestational-age birth was nearly the same as that for continuous smokers.

To assess the association of changes in smoking habits during pregnancy with infant birthweight, a linear regression analysis was performed. The regression model included as independent variables smoking group and the potential confounding factors noted above, as well as infant sex and gestational age. The model predicted that infant birthweight for women who stopped smoking by the second or third trimester was essentially identical to that predicted for nonsmokers. (Linear regression predicted that infant birthweight for those women who smoked only in the first trimester was 0.8 g lighter than that for nonsmokers, whereas those women who smoked in the first and second trimester had a predicted infant birthweight that was 1.6 g lighter than that for nonsmokers.) Women who smoked throughout pregnancy had infants who were 186 g lighter than those of nonsmokers (95% CI = 170, 202 g) whereas the infants of those who started smoking during the second or third trimester were, on average, 138 g lighter than the infants of nonsmokers (95% CI = 82, 194 g).

Given that smoking seems to act during the third trimester to increase the risk of term undersized birth, the next step was to examine the influence of amount smoked during the third trimester. Third trimester smoking was categorized as none, 1 to 5 cigarettes per day, 6 to 10 cigarettes per day, or more than 10 cigarettes per day. The frequency of small-for-gestational-age births according to quantity smoked during the third trimester (Table 4) indicates an increased risk for heavier smokers (χ^2 for trend, $P < .0001$). A logistic regression analysis that included all the potential confounding factors described above indicates odds ratios for the risk of undersized birth that increase with the amount smoked during the third trimester (Table 4).

Discussion

Our analysis of growth retardation among term infants born to smokers indicates that the risk can be reduced to that for nonsmokers if smoking is stopped before the third trimester, while the risk for those who do not smoke early in pregnancy but smoke in the third trimester will be similar to that for continuous smokers. Results from our analysis concur with those of Rush and Cassano.[2] MacArthur and Knox, on the other hand, found a more limited benefit with regard to infant birthweight for women who stopped smoking between 16 and 30 weeks.[3] In that study, however, women who stopped smoking later in pregnancy (later than 16 weeks) were of lower socioeconomic status than women who stopped earlier. Therefore, failure to adjust for socioeconomic status could account for the lower birthweights noted by these authors among infants of women who stopped smoking later in pregnancy.

Our results, taken together with those of the other studies, suggest that the effect of cigarette smoking on growth retardation occurs during the third trimester of pregnancy. This is also consistent with previous work demonstrating that for babies born early in the third trimester (at 30 to 31 weeks), smoking was not associated with the occurrence of growth retardation.[13]

Finally, our investigation indicates that while any smoking during the third trimester is associated with an increase in undersized birth, the risk also increases with the amount smoked. Studies of smoking and birthweight have not consistently noted a dose response. Rush and Cassano found that infants of heavy smokers (more than 15 cigarettes per day throughout pregnancy) had a crude mean birthweight that was 163 g lighter than infants of women who smoked fewer than 5 cigarettes per day[2]; women smoking 5 to 14 cigarettes had infants with birthweights similar to those born to the highest smoking group. Butler and Goldstein, in investigating smoking after the fourth month of pregnancy, found similar results with women smoking fewer than 5 cigarettes per day giving birth to infants with a mean birthweight that was 120 g lighter than those born to smokers of 20 to 30 cigarettes per day, whereas smokers of 5 to 20 cigarettes had infants with intermediate birthweights.[1] Control for confounders did not alter these findings. Hebel et al. examined birthweight according to amount smoked at the eighth month while controlling for confounding factors.[5] In contrast to our findings and to those cited above, they found no dose response for birthweight according to amount smoked at 8 months of pregnancy.

The potential impact on the occurrence of small-for-gestational-age birth if women did stop smoking during the third trimester is substantial. In this population, 24% of women (n = 2677) smoked during the third trimester and their risk of small-for-gestational age birth was 17.5%. If all the smokers in this cohort had stopped smoking (and their rate of undersized births was that of nonsmokers), the rate of small-for-gestational-age infants in the population overall would have been reduced from 10.6% to 8.5%, a 20%

reduction. This is consistent with the findings of Kleinman and Madans,[14] who estimated that low birthweight would decrease by 19% if all women stopped smoking, and with the findings of Kramer,[15] who estimated that, for a population in which 20% of women smoke, the etiological fraction for cigarette smoking as a cause for intrauterine growth retardation was 22%.

While smoking cessation programs have met with limited success, the evidence that smoking acts during the third trimester to retard fetal growth presents a compelling opportunity for intervention at a time when many women may be motivated to alter their behavior. Such interventions need to emphasize the importance of not relapsing and smoking late in pregnancy. It is also important to emphasize to women that these results should not be interpreted to mean that it is safe to smoke during early pregnancy. Smoking during pregnancy has been associated with a number of adverse pregnancy outcomes other than growth retardation, including placenta previa,[16] premature rupture of membranes,[17] and preterm birth,[18] and it is not clear when during pregnancy smoking acts to increase the risk of these events. Additionally, smoking cessation would result in long-term health benefits for the woman and would decrease her child's exposure to environmental tobacco smoke. □

Indicators for Monitoring the Growth of Peruvian Infants: Weight and Length Gain vs Attained Weight and Length

Ellen G. Piwoz, ScD, Guillermo Lopez de Romaña, MD, Hilary Creed de Kanashiro, MPhil, Robert E. Black, MD, MPH, and Kenneth H. Brown, MD

ABSTRACT

Objectives. To determine appropriate indicators and age intervals for growth monitoring in this population, the relationship between monthly weight and length indicators and nutritional status at 12 months was evaluated among 102 low-income Peruvian infants.

Methods. Cutoffs for defining adequate vs slow growth were obtained from published reference data, and sensitivities and specificities of each indicator were calculated.

Results. Low weight gain in early infancy, especially from 1 to 2 months, is useful for predicting low weight at 1 year (sensitivity = 81%, specificity = 65%, 25th percentile cutoff). Use of actual weight at 2 months, however, produces comparable results (sensitivity = 86%, specificity = 57%, 50th percentile cutoff). Monthly length gains were weak predictors of low length for age. Neither weight nor length gains accurately predicted the opposite form of undernutrition. Nonhuman milk consumption before 4 months and poor appetite from 3 to 12 months were related to low early weight gain and subsequent undernutrition.

Conclusions. Growth monitoring programs in this population should enroll infants at birth, monitor actual weight, promote exclusive breast-feeding and delayed introduction of nonhuman milk, and provide specific feeding advice to mothers of infants with frequentiy depressed appetites. (*Am J Public Health.* 1994; 84:1132–1138)

Introduction

Monthly growth monitoring has been promoted worldwide as an effective means for detecting growth faltering and preventing undernutrition in infants and young children.[1] These programs are intended to monitor weight gain, rather than attained size, and to provide timely feeding advice when infants fail to grow well.[2] Studies of the impact of growth monitoring have shown mixed results,[3–5] and the debate continues as to whether periodic weighing, charting of growth, and delivery of information on proper infant feeding and care is a wise use of scarce health resources in developing countries.[6–9]

The questions most frequently addressed in evaluations of growth monitoring programs are operational ones: (1) Can health workers be trained to weigh and record infant weights accurately? (2) Do mothers regularly attend the weighing sessions, and do they understand the information contained in the growth charts? (3) Do health workers understand the growth charts, and can they identify growth faltering when it occurs? (4) Do health workers provide nutritional counseling to mothers when it is requested and/or required? (5) Is the advice locally appropriate, compelling, and nutritionally sound? (6) Do mothers understand the advice and act on it? and (7) Does regular weighing with nutrition education improve infant growth and prevent undernutrition?

Failure of growth monitoring to reverse growth faltering may be due to one or more negative responses to the first six questions. In addition, in areas where health infrastructure is extremely poor, growth monitoring may not be effective because distribution and upkeep of scales is not efficient, opportunities for (re)training are limited, and supervision is nonexistent. In such locations, it has been suggested that development of basic health infrastructure should precede the initiation of growth monitoring programs.[6]

On the other hand, it has also been argued that growth monitoring programs may not appear to be effective because high-risk children are not specifically targeted.[10] In many programs, the goal is to regularly weigh all children younger than 2 to 5 years old, and specific attention, such as follow-up home visitation, is not directed at children until growth faltering is detected.[11] Nontargeted programs will appear to have little effect on nutritional status when large numbers of infants and children who are not at risk of undernutrition are included in the denominators of calculations to estimate program impact.

The need to identify sensitive and specific indicators of risk for developing undernutrition that can be easily used in community health programs is apparent, given the difficulty of implementing growth monitoring programs in some locations and the potential benefits of targeting high-risk infants and children within established programs. It would be useful to

know, for example, whether growth performance or other characteristics such as infant feeding practices, illness, or appetite history during specific early age periods predict undernutrition in later life. If this is the case, limited growth monitoring (during high-risk ages) could be offered in areas where health infrastructure cannot support comprehensive weighing and educational programs. Growth performance during high-risk periods could also be used to identify children who should be monitored more closely in programs already under way.

The purposes of this paper are to (1) describe monthly growth in a population of low-income Peruvian infants who were followed from birth to 12 months of age, (2) evaluate the sensitivity and specificity of different weight and length indicators for predicting undernutrition at 12 months, and (3) identify infant and family characteristics associated with indicators of high predictive power and with infants who were well nourished at 12 months despite slow growth during high-risk periods. The implications of these findings for growth monitoring programs are discussed.

Methods

Subjects and Field Methods

Data from a community-based longitudinal study of the relationships among nutrition, infection, and growth are used for this analysis. The study was carried out from July 1982 to June 1984 in Pueblo Joven Huáscar, a low-income, periurban community in Lima, Peru. The community and field methods have been described previously.[12–15]

One hundred fifty-six full-term, singleton infants with birth weights of 2500 g or more and no congenital abnormalities were enrolled in the study at birth. Low birthweight was uncommon in this population.[13] Of these infants, 3 dropped out in the first 2 weeks and an additional 34 dropped out during the first year. Those lost to follow-up remained in the study an average of 4.9 months (range = 1–10 months). Failure to complete the study was not related to weight or length gain during the monthly intervals available for study.

Body weights and recumbent lengths were measured by trained anthropometrists within 1 week of birth and at monthly intervals thereafter. Weights were determined with a portable, spring-balanced Salter scale that was sensitive to 100 g. Infants were weighed unclothed and weights were recorded as the mean of two separate, consecutive weighings. Lengths were measured to the nearest 0.1 cm with either a locally constructed length board (in homes) or a Harpenden-Holtain infantometer (in clinics). Periodic standardization exercises were held to minimize measurement error.

Length gain in the first month is not included in this analysis because most birth lengths were measured at local hospitals by multiple observers who were not affiliated with the study. Comparisons found that these measurements were less consistent and precise than the length data obtained by study anthropometrists during the first home visit.

Infants were visited at home thrice weekly to obtain information on their health status on that day and the 2 preceding days. Dietary intake information was obtained once or twice a month by 12-hour daytime observations with food weighing. Breast-milk consumption was measured by the test-weighing method.[16] Procedures for diagnosing and coding symptoms and determining dietary intake have been published previously.[13,14]

Information on usual feeding practices was obtained each month through a questionnaire administered to the infant's primary caretaker. Household sociodemographic information was obtained via questionnaire at the end of the study.

Analytic Methods

Growth increments were calculated in a two-step process. First, each infant's weight and length on his or her monthly birthday (30-day) were estimated by linear interpolation from two successive measurements, up to a maximum of 45 days apart. Increments were calculated as the difference between the interpolated values at the start and end of each 30-day period. Weight or length gain per day can be estimated from the data presented by dividing any monthly increment by 30.

Infants who were not measured within 15 days of their birthdays were assigned a missing value for the month and relevant increments. Although 119 infants completed the study, weight and length at 360 days could be calculated for only 102 infants meeting the criteria described above. Thus, the analyses related to nutritional status at 12 months (360 days) included a maximum of 102 infants.

All monthly comparisons use the maximum number of infants available for study during the time period being examined. Sample sizes vary from month to month, either because the timing of measurements did not meet the interpolation requirements or because of attrition.

Undernutrition at 12 months was defined as weight or length lower than the gender-specific National Center for Health Statistics (NCHS) median for this age[17] by 2 SD or more. These cutoffs are 8.1 kg and 70.7 cm for boys and 7.4 kg and 68.6 cm for girls. Differences in monthly growth among infants who were classified as poorly vs adequately nourished at 12 months, according to either indicator, were evaluated with Student's t test for continuous means.[18(pp54–56)] P values of less than .004 were considered statistically significant. This conservative level was selected by dividing .05 by 12, the number of comparisons performed with the same infants in each analysis.[19] P values between .004 and .05 were considered suggestive of relationships.

Cutoffs for defining adequate vs low gains and attained size were the 5th, 25th, and 50th percentiles of published studies (Guo et al.[20] for the first month, Roche et al.[21] for subsequent months). These cutoffs were used because they were derived from a subset of infants participating in the Fels Longitudinal Study, and Fels data were also used to generate the NCHS reference curves used in growth monitoring programs worldwide. Other percentile cutoffs were examined, but because absolute differences between them were small,[22] the results were not substantially affected and are therefore not presented here.

It is important to note that, for simplicity, the findings are presented in terms of the percentiles of the reference distributions used in the analysis, and not absolute weights or lengths. The 5th, 25th, and 50th percentiles of other studies (e.g., Tanner et al.[23]) do not correspond to the same absolute weight or length values. To avoid confusion among citations, results should be interpreted in terms of the gram or centimeter value being evaluated and not the percentile alone. These values may be obtained from the references cited.

The sensitivity, specificity, and positive and negative predictive values[24(p151)] of absolute size and gains above or below different cutoffs were generated from 2 × 2 tables, as defined in Table 1. The relative risk of developing undernutrition by 12 months, with 95% confidence interval (CI), was calculated for each cutoff by means of Epi-Info's STATCALC procedure.[25] Different indicators were compared by examining relative risks, by summing sensitivities and speci-

ficities, and by plotting relative operating characteristic curves (not shown). Relative operating characteristic curves plot sensitivity (y) against 1-specificity (x); the point that is highest from the line $x = y$ is assumed to be the best cutoff and indicator.[26]

Characteristics associated with slow growth (i.e., below the selected cutoff) during critical time periods and adequate size at 12 months despite slow growth during critical periods were identified by using Student's t test to compare the means of continuous variables for infants with low vs adequate gains. Differences in the distributions of categorical variables for both groups were determined with chi-square tests of homogeneity.[18] P values of less than .05 for the first set of comparisons and less than .10 for the second set of comparisons were considered statistically significant. The .10 value was used in the latter comparisons because of the small number of infants in this subgroup analysis (n = 45).

Results

Infants' monthly weight and length gains are presented in Table 2. A total of 27 infants (26.5%) were classified as undernourished according to either their weight (n = 21) or length (n = 18) at 12 months. Twelve infants were low in both weight and length (11.8%), 9 were low in weight only (8.8%), and 6 (5.9%) were low in length but not weight.

Compared with infants with adequate weight for age, infants with low weights at 12 months gained less weight during their first (average difference = 324 g, $P < .006$), second (average difference = 231 g, $P < .003$), fourth (average difference = 168 g, $P < .01$), fifth (average difference = 293 g, $P < .0001$), eighth (average difference = 145 g, $P < .04$), and eleventh (average difference = 137 g, $P < .03$) months and less length during their third (average difference = 0.53 cm, $P < .006$) and ninth (average difference = 0.52 cm, $P < .005$) months. Infants of low length for age gained less weight each month than did infants with adequate length at 12 months, but differences were small and relationships between weight gain and subsequent stunting were not statistically significant during any month. Somewhat surprisingly, length gains were also not significantly different for adequate-length vs stunted infants during any of the intervals studied.

The sensitivity, specificity, and predictive values for different definitions of adequate vs low monthly weight gain from birth to 6 months are presented in Table 3. These intervals were examined because, as shown above, low weight gain in early infancy was consistently related to low weight for age at 12 months. Similar statistics for length gain from 2 to 3 months are also presented because slow linear growth during this period was suggestive of a relationship with low weight for age. Similar comparisons using monthly gains and length for age are not presented because the relationships were weak and inconsistent. Results of these comparisons are mentioned when they are informative.

The results shown in Table 3 indicate that the risk of being low in weight for age at 12 months was greater for infants with low monthly gains from 1 to 5 months according to at least one of the cutoff points presented. For weight gain, the greatest relative risk and optimum sensitivity plus specificity were obtained by monitoring infants from 1 to 2 months of age. Infants who gained less than the reference 25th percentile (n = 45), or 1.08 kg for boys and 890 g for girls, were 5.31 times more likely to be undernourished at 12 months than were infants who gained more than these amounts (n = 54) during the same age period (95% CI = 1.93, 14.65). Weights at 1 month were less but not significantly different for infants who gained less (mean = 4.06 kg ± 574 g) or more (mean = 4.20 kg ± 558 g) than this cutoff. Sensitivities and specificities remained the same when infants were stratified by nutritional status at 1 month with the 25th percentile for weight in Roche et al.[21] used as the cutoff.

To elucidate why the 1- to 2-month age interval is critical, growth performance in previous and subsequent months was compared for all infants with weight gain above (n = 63) and below (n = 79)

the 25th percentile cutoff. This analysis revealed that infants with low gains from 1 to 2 months also tended to gain less weight, on average, from birth to 1 month ($P < .04$), from 2 to 3 months ($P < .04$), from 3 to 4 months ($P < .03$), and, to a lesser extent, from 4 to 5 months of age ($P < .09$). Mean differences ranged from 90 to 175 g. Monthly weight gains after 5 months were not significantly different for the two groups (mean differences ranged from 5 to 65 g). Length gains were lower among these infants from 1 to 2 months ($P < .002$) and from 2 to 3 months ($P < .03$); there were no differences in average length increments after 3 months.

Other variables associated with weight gain from 1 to 2 months are given in Table 4. Mothers of infants with low gains tended to be slightly older ($P < .04$) and more educated ($P < .03$) than mothers whose infants gained adequately. Although total energy intakes per kilogram of body weight were similar for the two groups during the dietary observations for the month, low gainers consumed less total energy from breast milk than did infants who gained adequately ($P < .005$). Furthermore, infants who gained slowly received 76% of their total energy from breast milk, compared with 86% for infants with adequate gains ($P = .06$). Low gainers were more likely to consume nonhuman milk than were infants who gained adequately ($P < .04$). Slow growth from 1 to 2 months was not associated with family income, the construction quality of the infant's home, or with the prevalence of diarrhea, fever, anorexia, or respiratory infections during the first or second month of life.

Identifying the traits of infants who gained slowly from 1 to 2 months but managed to achieve adequate weight status by 12 months ("positive deviants") may be useful for defining the nutrition education component of growth monitoring programs. Infants who gained slowly from 1 to 2 months but were not low in weight for age at 12 months had mothers with more than 5 years of formal education ($P < .03$) and lived in homes of better construction quality, specifically homes with latrines and/or cement floors ($P < .05$). In addition, they gained 71% more weight ($P < .001$) from 3 to 5 months of age (1.22 kg ± 395 g) than did infants who became undernourished (720 g ± 516 g), suggesting that this is another critical period for growth monitoring intervention.

Monthly illness prevalences for the positive deviants and infants who gained

[a]Cannot be calculated.

slowly at 1 to 2 months and were low in weight for age at 12 months were compared. As shown in Figure 1, the undernourished infants were consistently reported to have had anorexia (reduced appetite) more often from 3 to 12 months than the slow gainers who became well nourished. Although the positive deviant infants suffered from less diarrhea and fever, on average, than the undernourished infants, differences in the prevalences of these illnesses were statistically significant from 8 to 9 months only ($P < .05$). Total energy intake and energy from breast milk, nonhuman milk, and solid foods were not significantly different at any age for the positive deviants vs other infants. The undernourished infants, however, tended to consume more nonhuman milk from 3 to 8 months, and the well-nourished infants tended to consume more total energy and energy from solids from 9 to 12 months of age (data not shown).

Judgments about the use of attained weight vs weight gain for growth monitoring programs can be made by comparing Tables 3 and 5. Although the sensitivities and specificities obtained with attained weight are not, in a single interval, as large as those achieved using weight gain from 1 to 2 months and the 25th percentile until infants are 5 months old (25th percentile; 85% sensitivity, 79% specificity), from 2 months onward the relative risks of becoming undernourished and the sums of sensitivity plus specificity are greater for attained weight than for weight gain with either the 25th or the 50th percentile used as the cutoff.

Discussion

Governments and international agencies have been encouraging the development and implementation of community-based growth monitoring programs as a means of bringing infants and young children into regular contact with health care providers and of identifying growth faltering in its early stages. Evaluations of growth monitoring programs have produced mixed results, leading many to question whether such programs are worthwhile.[3–9]

This analysis was undertaken to evaluate the premise that monthly growth increments are useful predictors of undernutrition at 1 year of age and to identify critical age periods and definitions of inadequate gain for growth monitoring programs. Conditions and behaviors associated with slow growth during high-risk periods were identified.

The study infants' monthly weight gains were not related to their initial birthweights, which were all 2500 g or more. Weight gains during 4 of the first 5 months of life were consistently lower among infants who were identified as low in weight at 12 months than among those who were identified as having adequate weight.

Previous analyses of the patterns of growth in these infants suggested that mean weights were similar to the NCHS reference median until 5 to 6 months of

age[13] and to US breast-fed infants' mean weights until the second half of infancy.[27] Assessment of mean weight alone might lead to the conclusion that growth monitoring is not necessary in this population until infants are 6 months old. This analysis, however, suggests that growth faltering is a cumulative process that begins in early infancy. Weight gain during the second month is a critical period for growth monitoring because infants who gain slowly at this age continue to grow more slowly than other infants until 5 months of age and have a greater risk of being undernourished at 1 year.

Low weight gain in early infancy in this population appears to result from improper infant feeding practices, specifically the early introduction of nonhuman milk to the diet. Compared with infants who gained adequately, infants with low weight gains had older, more educated mothers who were more likely to feed them nonhuman milk in addition to breast milk. However, infants who gained slowly but managed to overcome early growth deficits had mothers with more than a primary-level education and lived in homes of somewhat better socioeconomic status and sanitary environment. For these infants, catch-up growth occurred during the 3- to 5-month period (90–150 days), when those who became well nourished gained 500 g more, on average, than the undernourished.

Infant appetite may have been an important reason why some of the infants who gained slowly in their early months were unable to overcome the growth deficit, whereas others were able to. Infants who gained slowly and remained underweight were reported to have reduced appetites two to three times more often than the "positive deviants" from 3 to 7 months, the age when they should be learning to become accustomed to solid foods. Studies of the epidemiology of anorexia in this population found that reported anorexia was usually preceded or accompanied by other symptoms, such as diarrhea and fever, and 25% to 35% reductions in energy intakes from solid foods.[28] These findings suggest the need to develop appropriate advice on feeding infants with depressed appetites to improve their growth performance.

The comparison of cutoff points and indicators suggests that although monthly weight gain in early infancy is useful for predicting low weight for age, it is not superior to attained weight as an indicator for predicting undernutrition in this population. Neither monthly weight gain nor length gain was accurate for predicting infant stunting.

The failure to find a strong and consistent relationship between monthly length increments and nutritional status at 12 months may have been due to several conditions. Successive monthly length increments were negatively correlated throughout most of infancy, suggesting measurement error, erratic growth, or both. The determinants of stunting in this population and the association between 2-month or 3-month length increments and subsequent stunting are currently being investigated. At present, monthly monitoring of infant length is not recommended.

The results of this analysis suggest that the first 5 months of life are the critical ages for monitoring infant growth and that growth monitoring programs in the population studied should enroll infants at birth or no later than 1 month. However, because weight gain was not superior to attained weight under the strictly supervised conditions of this study, and it is not likely to be better than attained weight in program settings where calculating the difference between two measurements inevitably produces greater error than recording a single weight, growth monitoring programs are advised to use attained weight rather than weight gain in this and similar Peruvian populations. The nutrition education that accompanies growth monitoring programs should focus on exclusive breast-feeding and delaying the introduction of nonhuman milk to improve growth in early infancy. Later on, when infants should be receiving solid food regularly, education should include information and advice on how to feed infants with poor appetites.

Caution is advised in drawing conclusions from this report about how growth monitoring programs should be conducted worldwide. The performance of these anthropometric indicators will vary with the prevalence of low birthweight, feeding practices, and other factors that affect growth patterns in infancy.[29]

In populations with many low-birthweight infants, for example, weight gain may be superior to attained weight, as is suggested in the literature.[2,11] Use of attained weight to target growth monitoring programs in these populations may result in a misuse of resources, because low-birthweight infants who are gaining well will be targeted for intervention while infants whose weights have not yet fallen below the designated weight cutoff but who are growing inadequately will not be reached.

The sensitivity and specificity of these indicators also depend on the outcomes being measured. In this study, the outcomes were low weight or length at 12 months. Results might be different if a different outcome (e.g., mortality) or low weight at a different age (e.g., 2 years) were being predicted. This paper illustrates the types of relatively simple analyses that can be performed to address whether growth monitoring programs, as they are currently promoted, are a worthwhile use of scarce health resources and how such programs can be targeted and thus made more efficient. Additional comparisons, using reliable growth data from other populations, must be carried out before guidelines for growth monitoring programs worldwide can be offered. □

Acknowledgments

These studies were supported primarily by the Diarrheal Disease Control Program of the World Health Organization and by the International Development Research Center. Additional funds were provided by the Office of Nutrition, US Agency for International Development (Dietary Management of Diarrhea Program, Cooperative agreement No. DAN-1010-A-00-5119-00).

The authors express their appreciation to the staff of the Instituto de Investigación Nutricional who collected and organized all of the data, and to Drs Stan Becker, Laura Caulfield, Marie Diener-West, and Jan Peerson for their thoughtful comments on this manuscript.

Ethnic Differences in Midwife-Attended US Births

Jennifer D. Parker, PhD

ABSTRACT

This study examined US ethnic differences in midwifery care from 1982 through 1989. After adjustment for maternal characteristics, Native American mothers were most likely, and White and Asian mothers were least likely, to obtain midwifery care. For these three groups, midwifery use increased rapidly in the period from 1982 through 1989. Compared with White mothers, Black and Hispanic mothers were more likely to be attended by a midwife; however, their use of midwives increased more slowly. Though the local availability of obstetricians and midwives may determine a woman's choice of care provider, these data suggest that cultural factors also play a role. (*Am J Public Health*. 1994;84:1139–1141)

Introduction

In 1989 nearly 150 000 US births were attended by midwives,[1] up from 60 000 a decade earlier.[2] Overall, women served by midwives differ from the general population of obstetric patients[2,3]; compared with all US births in 1988, for example, midwife-attended hospital births (87% of all midwife-attended births) were more common among women who were non-White, younger, less educated, and unmarried.[3] The use of midwives for perinatal care has been found to have no adverse effects on birth outcomes,[5–11] in spite of the dominance of women at higher risk for poor pregnancy outcomes among midwife patients. Because incorporating midwives into health care teams has been found to decrease costs,[5] determining which women may benefit from midwifery care could lead to cost-effective ways of improving maternal and infant health services.

This study investigates the ethnic differences associated with midwifery care. The objective was to document the association between maternal ethnicity and midwife attendance at birth from 1982 through 1989 and to determine how much of that association is explained by additional maternal characteristics. Although maternal characteristics associated with midwifery care have been reported,[2–4] differences between minority groups in the United States have not.

Methods

Natality files for 1982 through 1989, compiled by the National Center for Health Statistics, were used to examine US births attended by midwives.[12] To better compare physician- and midwife-attended births, this study population was limited to singleton births of infants weighing at least 2500 g. Births attended by someone other than a physician or midwife were excluded. Five categories of maternal ethnicity were defined by using the race and Hispanic origin data from the birth certificate.[12] Mothers of Hispanic origin were classified as Hispanic regardless of their race. In 1982, 23 states and the District of Columbia reported Hispanic origin of the mother; by 1989, 47 states reported Hispanic origin. However, even in the early 1980s, over 90% of Hispanic residents lived where Hispanic origin was recorded on the birth certificate.[13]

To control for the influence of additional maternal characteristics, the increased odds per year of midwife deliveries and the relative odds of midwifery use by ethnicity were estimated by using multiple logistic regression. Because the proportion of midwife-attended births is low, estimates from logistic regression correspond to the relative increase between years and the relative proportions among ethnic groups; however, these approximations slightly overstate trends for groups with more midwife utilization.[14] Regression models included maternal age, parity, education, first-trimester prenatal care, place of delivery (out of hospital vs in hospital), and marital status. Before 1989 maternal education was not recorded on birth certificates in California, Texas, and Washington; in 1988 and 1989, New York State (outside of New York City) did not collect information on

education. This analysis was limited to the remaining states and the District of Columbia. Births missing information about maternal characteristics (fewer than 2% of the remaining births) were also excluded.

Results

Overall, 3.99% of singleton infants weighing more than 2500 g were delivered by a midwife in 1988, compared with 2.09% in 1982. An increase in midwife-attended births was apparent among all groups of women; however, the rate and pattern of increase differed by ethnicity (Figure 1). In 1989, 90% more White, 70% more Native American, 60% more Hispanic, 50% more Asian, and one third more Black women delivered with midwives than in 1982.

On average, midwifery care during this period increased over 7% per year among Native American, Asian, and White mothers, but increased less rapidly among Black and Hispanic mothers (Table 1). The impact of maternal characteristics varied by ethnicity. For example, after adjustment for demographic characteristics, the increased odds of being attended by a midwife rather than a physician dropped by almost one third among Hispanic mothers, but changed little among Native American mothers.

In spite of the rapid increase in midwife-attended births to White mothers during the 1980s, these mothers delivered with midwives less frequently than mothers of all other ethnic backgrounds (Table 2). Except for Asian mothers, adjustment for maternal factors reduced the ratio between White and non-White mothers by approximately 10%. However, Native American mothers remained approximately five times more likely and Hispanic mothers over twice as likely to be attended by a midwife than White mothers.

Discussion

This study documents ethnic differences in midwifery utilization throughout the 1980s in the United States. Compared with other mothers, for example, Native American mothers were the most likely, and White mothers were the least likely, to be attended by a midwife. However, among both groups the use of midwives increased rapidly during that time. Maternal factors, such as education and marital status, explained few of these differences; the unadjusted and adjusted estimates of midwife use were similar. The geographic distributions of ethnic groups, as well as of perinatal care providers, within the United States likely determined most of these differences.[3,4,8,9]

However, cultural preferences for physicians or midwives may also have

contributed to these findings. Acceptance of midwives may have expanded more rapidly among White mothers than among Black mothers, for example. Although White mothers were the least likely to be attended by a midwife, their use of midwives rose during the 1980s. This increase led to a rising proportion of midwife-attended White births during that time.[3]

Reports from 1989 birth certificates document maternal differences by type of midwife provider.[1,4] Unfortunately, before 1989, birth certificates were not that detailed; therefore, the term "midwife" in this study refers to both certified nurse-midwives and midwives with other training. Furthermore, Adams reported that more than 10% of certified nurse-midwives do not sign birth certificates,[15] also affecting comparisons between midwife and physician patients.

Nonetheless, the relatively high use of midwives by minority women and the overall increase in midwife-attended births throughout the 1980s suggest that midwifery is expanding to fill health care gaps. An understanding of ethnic differences in midwifery utilization may assist planners in effectively planning obstetric services in local communities. □

Exposure to Hair-Coloring Products and the Risk of Multiple Myeloma

Lisa J. Herrinton, PhD, Noel S. Weiss, MD, DrPH, Thomas D. Koepsell, MD, MPH, Janet R. Daling, PhD, John W. Taylor, MD, Joseph L. Lyon, MD, G. Marie Swanson, PhD, and Raymond S. Greenberg, MD, PhD

ABSTRACT

An interview study of persons diagnosed with multiple myeloma between 1977 and 1981 and suitable control subjects was conducted to test the hypothesis that exposure to hair dyes increases the risk of multiple myeloma. Among women, there was little evidence that prior regular use of hair dyes (odds ratio [OR] = 1.0; 95% confidence interval [CI] = 0.70, 1.4) or prior employment as a hairdresser (OR = 1.1; 95% CI = 0.43, 2.7) increased risk; however, the former comparison was limited by the lack of detailed information concerning the exposure. Among men, there was a modest association of regular use of hair dyes (OR = 1.5; 95% CI = 0.75, 2.9) with myeloma, but this was based on a small number of exposed persons. (*Am J Public Health.* 1994;84:1142–1144)

Introduction

We sought to investigate the hypothesis that exposure to hair dyes is associated with the risk of multiple myeloma by analyzing data from a population-based case-control study in which prior regular use of hair dyes and prior employment as a hairdresser were ascertained.

Methods

The data analyzed here were collected as part of a population-based case-control study of multiple myeloma that has been described previously.[1] Briefly, case patients under 82 years of age with incident multiple myeloma diagnosed from 1977 to 1981 were identified through cancer registries participating in the Surveillance, Epidemiology, and End-Results program in four geographic areas. Control subjects, matched so that their distributions of age, sex, and race were similar to the case patients, were identified using area sampling methods and random-digit dialing. A total of 689 case patients and 1681 control subjects, representing 89% and 83% of all eligible subjects, respectively, were identified.

Trained professional interviewers administered a standard questionnaire to 64% of the case patients and 99% of the control subjects. For the remaining subjects, who had either died or were ill, information was obtained from a spouse or relative (proxy respondent). Each subject's exposure status was determined up to a reference date, which was the date of diagnosis for the case patients and 1 year before the date of interview for the control subjects. Lifetime occupational histories were coded using the 1970 US Census codes, while prior regular use of hair dyes was determined from responses to the question: "Have you ever regularly used hair dyes?" Odds ratios (ORs) and exact 95% confidence intervals (CIs) were computed using logistic regression,[2] with adjustment for the matching variables of age (continuous), sex, race (White, other), and study center (Seattle, Utah [several counties], Detroit, Atlanta). Adjustment was also made for educational attainment (did not complete high school, high school graduate) because its inclusion in the logistic regression model influenced the odds ratios somewhat.

Results

Among self-responding women, a similar proportion of case patients and control subjects reported prior regular use of hair dyes (OR = 1.0; 95% CI = 0.70, 1.4) and prior employment as a hairdresser (OR = 1.1; 95% CI = 0.43, 2.7) (Table 1), and there was no consistent trend of increasing myeloma risk with increasing duration of employment (*P* trend, .558). Among self-responding men, there was a modest association of myeloma risk with reported prior use of hair dyes (OR = 1.5; 95% CI = 0.75, 2.9) and prior employment as a hairdresser (OR = 2.2; 95% CI = 0.18, 27), although both estimates of excess risk were based on small numbers of exposed subjects and were well within the limits of chance given no true association. There was little difference in the results when data from proxy respondents were included in the analysis.

At the time of the study, Lisa J. Herrinton, Noel S. Weiss, Thomas D. Koepsell, and Janet R. Daling were with the Department of Epidemiology, University of Washington, and the Division of Public Health Sciences, at the Fred Hutchinson Cancer Research Center, Seattle, Wash. Dr Herrinton is currently with Kaiser-Permanente in Oakland, Calif. John W. Taylor is with Group Health Cooperative of Puget Sound, Seattle. Joseph L. Lyon is with the School of Medicine, University of Utah, Salt Lake City. G. Marie Swanson is with Michigan State University's Cancer Center, East Lansing. Raymond S. Greenberg is with the School of Public Health, Emory University, Atlanta, Ga.

This paper was accepted October 21, 1993.

Discussion

An important limitation of these findings concerns the lack of precision in the question concerning personal use of hair dyes. A wide range of hair-coloring products may have elicited an affirmative response to the question concerning regular use of hair dyes, thereby obscuring a true exposure–disease relationship with a specific chemical. Also, some individuals may have incorrectly given a negative response to the question; such nondifferential misclassification also would have obscured any true association. In addition, our power to detect an association with a history of employment as a hairdresser was limited, as reflected by the width of the confidence intervals observed for these comparisons.

Experimental evidence that components in hair-coloring products cause cancer has been reviewed by Zahm and colleagues.[3] Briefly, the product formulations vary by manufacturer and over time. Darker formulations generally contain greater concentrations of dyes, while permanents contain oxidants that may affect the absorption of particular chemicals. Hairdressers may be more highly exposed to the chemicals in hair dye than are personal users of hair-coloring products, although an assessment of the relative exposures received by these two groups has not been conducted. Skin-painting experiments have given evidence for exposure through dermal absorption; it is also reasonable to believe that there is exposure through inhalation and inadvertent ingestion.

There have been four studies concerning the relationship between exposure to hair dyes and multiple myeloma risk. Two, using proportional measures of incidence[4] or mortality,[5] found evidence for an association with a history of employment as a cosmetologist or hairdresser (proportional incidence ratio, 467[4]; proportional mortality ratio, 619[5]). Follow-up of a cohort of 13 650 persons holding licenses for 5 years or longer prior to 1971 to practice cosmetology in Connecticut gave no evidence that myeloma risk was increased relative to that in the general Connecticut population (standardized incidence ratio, 0.69; 95% CI = 0.14, 2.0).[6]

However, in a population-based case–control study conducted in eastern Nebraska between 1983 and 1986, evidence was found that personal use of any hair-coloring products, and particularly permanents, was associated with myeloma risk (women: OR = 1.8; 95% CI = 0.9, 3.7; men: OR = 1.8; 95% CI = 0.5, 5.7), and there was a fairly consistent trend in risk with increasing duration of use of the products.[3] Two important differences between the Nebraska study and our own may account for the differences in our results. First, our ascertainment of personal use of hair-coloring products was limited and may have caused us to underestimate the association. As described previously, we did not obtain the names of the specific products used or information concerning color shade or permanence. The second difference concerns the sampling frames of the two studies: the Nebraska study included case patients diagnosed several years later than those in our study. It is possible that the time frame during which the Nebraska study was conducted, following reports that use of hair dyes may cause cancer, may have resulted in some degree of ascertainment bias. Prior regular use of hair dyes was associated not only with the occurrence of multiple myeloma in that study, but also with non-Hodgkin's lymphoma and Hodgkin's disease (although not with chronic lymphocytic leukemia). While it is possible that the etiologies of these three malignancies have some factors in common, it is also possible that the odds ratios for the associations of the individual malignancies with a history of using a hair-coloring product were all influenced by recall.

Our study provides little evidence that exposure to hair dyes increases myeloma risk. Nonetheless, because exposure to the chemicals present in hair-

A Decision-Analytic Approach to Postexposure Rabies Prophylaxis

Scott B. Cantor, PhD, Richard D. Clover, MD, and Robert F. Thompson, MD

ABSTRACT

The risks and benefits of postexposure rabies prophylaxis were analyzed from clinical and economic perspectives. A decision-analytic model was constructed by using probability and outcome data from the literature and the state health department. Health outcomes were measured in quality-adjusted life years. In the base case (overweight adult male), treatment is optimal when the probability of animal rabidity is greater than 1 in 2000. Sensitivity analysis showed robustness in the treatment decision; however, the incremental cost-effectiveness ratio ($140 000/quality-adjusted life year) is sensitive to the rabidity probability. Treatment is optimal from the patient's perspective; however, it may not be cost-effective when the probability of rabidity is low. (*Am J Public Health.* 1994;84:1144–1148)

Introduction

Since the development of domestic animal control programs in the 1950s, the number of cases of human rabies in the United States has decreased from approximately 20 in 1952 to 0–5 per year today.[1] However, the decision to provide postexposure prophylaxis against rabies is still a frequent problem for public health departments, emergency rooms, and primary care physicians.[2] Appropriate management of persons possibly exposed to rabies depends on several factors, including the epidemiology of the disease, routes of transmission, and the perceived risk of infection. McCombie states that immunization decisions are affected not only by medical indications but also by factors such as reducing the patient or clinician's anxiety, preventing psychosomatic illness, reducing the fear of malpractice litigation, and fulfilling the clinician's need to intervene.[3] He suggests that formal medical decision analysis will lead to optimal treatment and more cost-effective decisions.

This article presents a decision analysis of the dilemma of whether or not to administer postexposure prophylaxis for rabies based on currently available medical information. The clinical case of an overweight 56-year-old White man who had been bitten by an opossum prompted this analysis.

Methods

A decision-analytic model was created to structure the decision whether or not to offer postexposure rabies prophylaxis.[4] As shown in Figure 1, treatment can be withheld or offered. If treatment is withheld and the animal was rabid, then the patient will die. If treatment is withheld and the animal was not rabid, normal life expectancy will follow.

Postexposure rabies immunization is assumed to be effective. However, adverse side effects can occur (Table 1). Minor reactions do not last longer than 1 month[5,6]; major reactions last no more than 3 months.[7–9]

A third strategy is plausible, in which the patient can be observed for 7 days to determine whether further treatment is necessary. However, the Centers for Disease Control and Prevention insist that treatment decisions about rabies must be made immediately.[10]

Probability of Rabidity

Once it has been established that an infection might have been transmitted

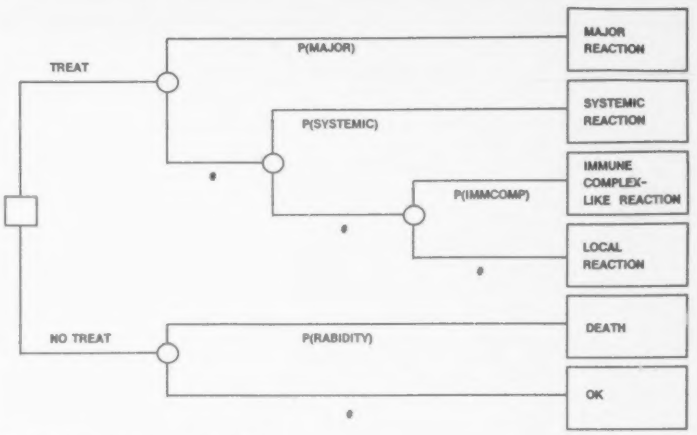
from animal to human through an open wound or bite, the likelihood of rabidity needs to be evaluated. The type of animal and the regional experience with rabies will determine the probability of rabidity. The municipal or state health department can provide data regarding the rabies status of animals recently tested.

However, an interesting but difficult methodological problem occurred in our estimation of the probability of rabidity when all previously examined animals were found not to be rabid (Texas Department of Health, unpublished data, 1992). In this case, the classical statistics approach of using the maximum likelihood estimate of zero did not provide a satisfactory answer. Decision analysis demands an explicit probability estimate; therefore, the alternative Bayesian approach of prior-to-posterior updating was chosen.[11]

In the Bayesian approach to estimating an unknown population parameter, the sample evidence is combined with a prior probability distribution, and the mean of the posterior probability distribution is computed for use as the parameter estimate. In this case, we needed to determine an initial prior distribution of the probability that a particular animal is rabid. The beta distribution is a good choice because of its ease of use and applicability to problems with an unknown population proportion. Specifically, if the prior probability distribution is beta, then the posterior probability distribution will also be beta with the mean equal to $(r + a)/(n + a + b)$, where a and b are the parameters of the beta distribution, n is the number of samples taken, and r is the number of rabid animals found in the sample.[12]

Without any previous guidance to estimate the probability of rabidity, we might have considered the beta distribution with parameters $a = 1$ and $b = 1$ (uniform distribution) as the prior distribution of the probability of rabidity. To err on the side of not treating, we chose the beta distribution with parameters $a = 1$ and $b = 101$ for the prior distribution. After we incorporated our sample of 752 nonrabid opossums, we computed that the posterior probability that the opossum in question was rabid was 1/854. This latter assumption was used in the base case analysis.



Note. # = complementary probability.

FIGURE 1—Decision-analytic model of the decision to administer postexposure rabies prophylaxis.

TABLE 1—Outcomes of the Postexposure Rabies Prophylaxis Decision

Outcome	Conditional Probability[a]	Duration of Adverse Reaction	Expected No. of Physician Visits	Vaccine	Complications
Treatment					
Local reaction (pain, erythema, swelling, or itching at injection site)	0.72	1 mo	1.5	Yes	None
Systemic reaction (headache, nausea, abdominal pain, muscle aches, dizziness)	0.22	1 mo	2.5	Yes	None
Immune complex–like reaction	0.08	1 mo	2.5	Yes	None
Major neurological reaction (resembling Guillain-Barré syndrome and other nervous system disorders)	0.000001	3 mo	4.0	Yes	14 hospital days
No treatment					
Animal rabid (death)			1.0	No	30 hospital days
Animal not rabid (normal survival)			1.0	No	None

Note. Physician office visit costs are considered in addition to hospital costs.
[a]See Figure 1.
Sources. Probability data are from references 7–10. The expected numbers of physician office visits are based on authors' estimates. Average length of stay data are based on reference 18.

Outcomes

The outcomes in the decision-analytic model are expressed in quality-adjusted life years.[13] In the case of an untreated bite from an animal that was not rabid, then the standard life expectancy is used[14]; for an untreated rabid bite, it is assumed that the quality-adjusted life expectancy is 0 quality-adjusted life years.

TABLE 2—Quality-Adjusted Life Expectancy Based on the Time Trade-Off Method: Outcomes after Postexposure Rabies Prophylaxis

Adverse Effect	Quality-Adjusted Life Expectancy
Local reaction	0.99 · (1/12) + (11/12) + (NORMLE-1)
Systemic reaction	uSYS · (1/12) + (11/12) + (NORMLE-1)
Immune complex–like reaction	uIMM · (1/12) + (11/12) + (NORMLE-1)
Major neurological reaction	uMAJ · (3/12) + (9/12) + (NORMLE-1)

Note. The amount of standard life expectancy is assigned the variable NORMLE. The variables uSYS, uIMM, and uMAJ represent the time trade-off utilities for systemic, immune complex–like, and major neurological reactions. The first two terms of each expression represent the quality-of-life adjustment for the first year of life after prophylaxis. The third term represents the remaining years of normal life expectancy.

TABLE 3—Quality-of-Life Adjustment Weights: Time Trade-Off Method of Utility Assessment

Adverse Effect	Mean[a]	SD	Median
Local reaction	0.99	. . .	. . .
Systemic reaction	0.56	0.19	6 mo (0.50 y)
Immune complex–like reaction	0.57	0.23	7 mo (0.58 y)
Major neurological reaction	0.31	0.20	3 mo (0.25 y)

Source. Survey of 15 University of Texas Department of Family Medicine faculty, residents, and students. Quality-of-life adjustment for local reaction was assumed to be .99.
[a]Fractional portion of 1 year in perfect health that is equivalent to 1 year in substandard health state.

TABLE 4—Results of Sensitivity Analysis for Base Case of 56-Year-Old White Male

Probability Variable	Threshold Probability
Rabidity	.0005
Systemic reaction	.5997
Immune complex–like reaction	.5378
Major neurological reaction	.0778
Time Trade-Off Parameter (Quality-of-Life Adjustment Weight)	**Threshold Value**
Local reaction	0.7803
Systemic reaction	Not found
Immune complex–like reaction	Not found
Major neurological reaction	Not found

We did quality-of-life utility assessment using the time trade-off method.[15] A sample of 15 faculty, residents, and medical students in a university hospital department of family medicine were asked, in questionnaire format, the number of months in perfect health they perceived to be equivalent to 12 months in a reduced health state. The mean responses were used to compute the quality-adjusted life expectancy for each outcome (Table 2).

Costs

Cost data were estimated from a national survey of hospital financial and operating statistics.[16] Data are based on costs, not charges, of all hospital services including overhead.[17] For all admissions, the national average cost per discharge was divided by the average length of stay to approximate an average cost of $722 per hospital day.

For every possible outcome modeled, the expected number of physician visits and length of hospital stay were estimated by a panel of academic family physicians. The more severe the adverse reaction, the greater the number of visits and the longer the hospital stay[18] (Table 1).

The cost of the vaccination is high and is proportional to the total body weight of the patient. For an overweight man weighing 135 kg, the vaccination series costs $606. For purposes of sensitivity analysis (see below), it was determined that the cost of vaccinations for a child weighing 30 kg would be $383 (Pasteur Mérieux, Lyons, France).

We analyzed the cost-effectiveness from a societal perspective using the outcome measure of dollars per quality-adjusted life year gained. We discounted costs and effectiveness at a 5% rate. In this model, there are no future costs; however, the future benefits of normal life expectancy were discounted to fairly compare the cost-effectiveness of postexposure rabies prophylaxis with other therapeutic interventions.[19]

Software and Sensitivity Analysis

Analysis was performed with SMLTREE 2.9 software.[20] Sensitivity analysis was performed to determine whether the optimal decision would be robust to changes in the value of the probability and utility parameters. Additional analyses were performed for a hypothetical 9-year-old Black female patient. The alternative scenario of a bitten child is a more frequent occurrence in primary care and provides a comparison.

Results

Table 3 summarizes the results of the time trade-off survey. Surprisingly, the immune complex-like reaction was perceived as nearly equivalent to the minor systemic reaction. However, the neurologic reaction was rated worse than either minor reaction, consistent with what was anticipated.

We then used the survey results to determine the optimal strategy, using the criterion of expected quality-adjusted life-year maximization. The treatment strategy yielded 19.989 expected quality-adjusted life years; the no-treatment strategy yielded 19.977 expected quality-adjusted life years. Thus, treatment is preferred to no treatment by approximately 4.5 quality-adjusted life days.

One-way sensitivity analysis revealed that treatment would be the optimal decision when the probability of animal rabidity was greater than 1 in 2000 (Table 4). Threshold values for the other probabilities of adverse reaction were also found to be much greater than the base case parameters.

Changes in individual utility parameters also had no effect on the optimal decision, with the exception of the time trade-off parameter for local reaction. If 1 year of having an adverse local reaction were considered equivalent to less than 9 months of perfect health, then no treat-

ment would be the optimal decision. Thus, when quality-adjusted life years are used as the outcome measure, treatment is a robust optimal strategy.

An economic analysis of the treatment decision can be based on the incremental cost-effectiveness ratio of treatment compared with no treatment, defined as the difference in costs divided by the change in quality-adjusted life expectancy. As shown above, it is beneficial from the patient's perspective to treat; however, treatment is costly. On an expected cost basis, the treatment strategy is more expensive than the no-treatment strategy ($721 vs $90). From the societal perspective, the incremental cost-effectiveness ratio was approximately $140 000 per additional quality-adjusted life year gained. In comparison, previously analyzed interventions such as treatment of moderate hypertension and screening for osteoporosis have been shown to be cost-effective at a cost of $25 000 to $40 000 per quality-adjusted life year gained.[21,22]

However, the cost-effectiveness ratio is very sensitive to the probability of rabidity. Table 5 shows the variability of the cost-effectiveness ratio for many animals. For high probabilities of rabidity, treatment is a dominant strategy, saving more lives at a lower expected cost by avoiding the likely expensive hospitalization of a dying patient. As the probability of rabidity decreases, the cost-effectiveness ratio increases exponentially. For low probabilities of rabidity, no treatment is a dominant strategy; treatment is more expensive than withholding treatment with no increase in life expectancy.

When the same analyses were performed for a 9-year-old Black female, the results changed—but not dramatically. In this case, the threshold probability of rabidity was 1 in 5000. Less than 1 quality-adjusted life month was expected to be gained by treatment; however, the expected benefits from treatment cost less than $32 500 per quality-adjusted life year gained. The health benefits and cost-effectiveness of treatment depend not only on the probability of rabidity, but also on the patient's age and body weight.

TABLE 5—Sensitivity Analysis of Cost-Effectiveness Ratio Based on Probability of Animal Rabidity

Probability of Rabidity[a]	Animal	Incremental Cost-Effectiveness Ratio
1 in 3	Skunk	TREAT dominating strategy[b]
1 in 10	Bat	TREAT dominating strategy[b]
1 in 100	Dog (wild)	$3 662 per QALY gained
1 in 200	Cat	$10 028 per QALY gained
1 in 854	Opossum	$139 988 per QALY gained
1 in 1000		$278 144 per QALY gained
1 in 10 000		NO TREAT dominating strategy[c]
1 in 100 000		NO TREAT dominating strategy[c]

Note. QALY = quality-adjusted life year.
[a]Probability of rabidity is based on unpublished data from the Texas Department of Health, 1987–1991.
[b]TREAT is the dominating strategy because costs are lower and expected QALYs are higher than those associated with the NO TREAT strategy (based on high probability of rabidity).
[c]NO TREAT is the dominating strategy because costs are lower and expected QALYs are higher than those associated with the TREAT strategy (based on low probability of rabidity).

Discussion

A decision-analytic model of postexposure rabies prophylaxis has not been previously published. Because the vaccine has potentially serious, albeit rare, adverse effects, it is erroneous to assume that vaccinations should always be administered. Thus, it is important to approximate the probability of rabidity. Formal decision analysis is an important, appropriate methodology to guide clinical management.

For many animal species, the probability of a particular animal's being rabid is very slight. If physicians can reduce the tendency to overestimate the probabilities of unlikely outcomes,[23] then the bias to overtreat may be reduced. With better understanding of small probabilities, clinicians can make better decisions.

The small differences in quality-adjusted life expectancy for the two strategies may lead some to the conclusion that the postexposure rabies prophylaxis decision is a "toss up."[24] Kassirer and Pauker suggest that exogenous factors not considered in the original model should then be included. In this case, patient risk aversion,[25] patient anxiety,[26,27] and physician preferences[28] would all support the decision to treat.

This case exemplifies a classic dilemma of medical decision making: what may be optimal treatment for the patient may not be cost-effective for society. In the case of the decision to treat after potential rabies exposure, the decision-analytic model showed that treatment was indicated, even though the gain in quality-adjusted life expectancy was less than 1 month. As was shown in the threshold analysis, treatment was indicated for probability of rabidity greater than 1 in 2000 for the adult case and 1 in 5000 for the child case. However, based on an incremental cost-effectiveness analysis, the monetary amount needed to achieve that benefit is significant, although it may be barely consistent with other therapeutic interventions considered to be cost-effective. □

Mass Media and School Interventions for Cigarette Smoking Prevention: Effects 2 Years after Completion

ABSTRACT

The long-term cigarette smoking prevention effects of mass media and school interventions were assessed. Adolescents in two communities received both mass media and school interventions; those in two matching communities received only school interventions. Surveys of 5458 students were conducted at baseline in grades 4 through 6 and 2 years after the 4-year interventions were completed, when students were in grades 10 through 12. Students exposed to the media-plus-school interventions were found to be at lower risk for weekly smoking (odds ratio = 0.62, 95% confidence interval = 0.49, 0.78) than those receiving school interventions only, indicating that the effects of the combined interventions persisted 2 years after the interventions' completion. (*Am J Public Health.* 1994;84:1148–1150)

Introduction

We previously reported on significant reductions in adolescent cigarette smoking achieved by mass media interventions combined with school programs.[1,2] Since other smoking prevention studies have shown that effects were lost over time, we conducted additional surveys 2 years after these interventions ended.[3,4]

Methods

Baseline surveys were administered to 5458 students in grades 4 through 6 from four communities in the United States. Those in two communities received mass media and school interventions for 4 years; those in two matched communities received only the school interventions. Interventions were focused on cigarette smoking prevention.[1,2] When these students were in grades 10 to 12, we attempted to follow up all cohort members.

Study Samples

Within the four study communities, equivalence of treatment groups was increased by selecting schools in census tracts having characteristics indicating higher risk for cigarette smoking. In media-plus-school tracts, 68% of adults

were high school graduates, and median household income was $14 186. In school-program-only tracts, 74% were graduates and household income was $14 994.

The full-exposure sample consisted of cohort members participating in all six school surveys; this sample was assumed to have received the complete intervention. The complete-follow-up sample included all cohort members assessed in grades 10 to 12 regardless of survey participation during intervening years; these students received varying intervention exposure because some moved away or left school after the baseline survey.

Data Collection and Measurement

All school surveys were conducted by the University of Vermont. For cohort members who were not present for the follow-up school survey, telephone interviews were conducted by the University of Minnesota.[5] The primary outcome measure assessed cigarettes smoked in the past week; responses greater than zero were classified as weekly smokers. Two additional smoking measures, daily smoking and self-selected smoking category, were included to examine consistency of results.[6,7] Saliva samples were obtained during school surveys as a bogus pipeline procedure to encourage more accurate self-reports.[8] Self-reports of alcohol use were measured to assess substance use behaviors not targeted by the interventions.

Statistical Analyses

The study design was based on the individual as the unit of analysis. For analyses based on this perspective, stepwise logistic regression was used to assess treatment effects while adjusting for potential confounding variables. For analyses concerned with the complete-follow-up sample, additional predictors were included for type of follow-up survey and years of intervention exposure. Inclusion of variables was based on significance of the F-to-enter ($P < .05$) and improvement in model fit (Hosmer-Lemeshow test).

Consistency between units of allocation to treatment and units of analysis has been emphasized in the recent program evaluation literature.[9] Because study communities were assigned to treatment groups, analyses of variance based on this perspective are presented. These analyses have low statistical power because of the small number of community units available. Community was considered a random factor nested within treatment; school, a random factor nested within community; and individual, a random factor nested within school. Significance associated with treatment differences was determined using community within treatment as the error term.[10]

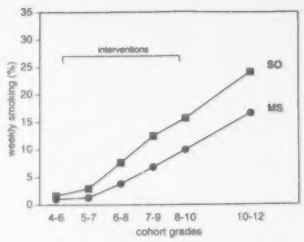

FIGURE 1—Weekly smoking among those participating in all six school surveys (full-exposure sample) in the media-plus-school (MS) and the school-program-only (SO) treatment groups (n = 2086).

Results

Of the 5458 students participating in baseline surveys, 38% (n = 2086) participated in the five subsequent school surveys and constituted the full-exposure sample; 86% (n = 4670) participated in surveys of grades 10 to 12 and constituted the complete-follow-up sample (Table 1). In the full-exposure sample, the media-plus-school group had a larger proportion of females, a group at higher risk for becoming smokers, than the school-program-only group. In the complete-follow-up sample, the media-plus-school group also were more likely to report sibling smokers.

Changes in weekly smoking for the full-exposure sample are shown in Figure 1. When 1991 weekly smoking was regressed on potential explanatory variables, five predictors met the inclusion criteria (Table 2). The odds ratio for being a smoker in the media-plus-school group was 0.62, indicating reduced risk. Similar models were obtained for the alternative smoking measures. Analyses of variance based on community as the analytic unit showed significant differences between treatment groups both before adjusting for covariates ($F_{1,2} = 24.6$; $P = .04$) and after adjustments ($F_{1,2} = 92.0$; $P = .01$).

When 1991 weekly smoking was regressed on potential explanatory variables in the complete-follow-up sample, five predictors again met the inclusion criteria (Table 2). In this model, the odds ratio for being a smoker in the media-plus-school group was 0.79. For analyses based on community as the unit, this difference was not statistically significant ($F_{1,2} = 4.38$; $P = .17$).

Self-reports of alcohol use were examined using similar logistic regression models. No treatment effects were observed.

Discussion

These results extend earlier findings of the smoking prevention efficacy of media and school interventions in two ways: (1) effects persisted 2 years after interventions ended; and (2) effects were observed among a more diverse sample of the original cohort.

The treatment groups had reasonably equivalent baseline characteristics but tended to show the media-plus-school group to be at higher risk for smoking; census tracts from which this group were drawn also showed higher population risks for smoking. Intervention effects were specific to cigarette smoking and did

[a]*P* values represent significance of Hosmer-Lemeshow goodness-of-fit test.

not reflect a general proneness toward less substance use in the media-plus-school group. These findings confirm that sample differences were unlikely explanations for observed effects.[1] Confidence in the findings was increased by the consistency of results across different smoking measures.

For the full-exposure sample, both individual and community-based analytic approaches provided evidence of significant treatment effects. For the complete-follow-up sample, the primary analysis showed significant effects while the more conservative approach did not. The strength and specificity of the effects, their consistency, and their agreement with earlier results, however, support a conclusion that treatment differences were observed in the latter sample.

These results should be generalizable despite demographic differences between study areas and the US population. Census data indicate that the cohort represented a lower-income sector of the US adolescent population. High levels of cohort recruitment and retention provided an unusually complete picture of long-term effects within this group.

Other studies have evaluated multifaceted smoking prevention approaches.[7,11–14] This group of studies suggests that school smoking prevention programs can have substantial effects when supported by efforts outside of schools to influence perceptions of peer and community norms. The present study shows that sustained smoking prevention effects can be achieved efficiently through schools and mass media, two of the most powerful influences on young people. □

Counseling Adolescents for Smoking Prevention: A Survey of Primary Care Physicians and Dentists

David I. Gregorio, PhD, MS

ABSTRACT

Pediatricians, family practitioners, and dentists were questioned in the spring of 1992 about whether they counseled adolescent patients (10 through 18 years old) not to smoke. Of the 674 questionnaires distributed, 443 (66%) were returned and analyzed. Most practitioners could not estimate cigarette use among their adolescent patients. Prevention counseling occurred infrequently, and least often among younger patients. Physicians were more likely than dentists to counsel adolescents. The data highlight the need for continuing training of primary health care practitioners about the importance of counseling adolescents not to smoke. (*Am J Public Health.* 1994;84:1151–1153)

Introduction

After 3 decades of intense warnings about the hazards of tobacco use, smoking initiation rates among our nation's youth remain alarmingly high. Currently, one in six of our nation's children may become regular smokers, and one quarter of them, or 5 million individuals, will die unnecessarily from their addiction.[1] Prevention of smoking initiation is an essential strategy to lessen the number of persons addicted to nicotine and avoid the health effects of that habit.

It has long been appreciated that primary health care providers can play significant roles in helping young patients to avoid the use of tobacco.[2,3] They are knowledgeable about the hazards of smoking, they often serve as powerful role models,[4] and they are likely to have frequent contact with these patients.[5] Recently issued Guidelines for Adolescent Preventive Services recommend that persons between the ages of 11 and 21 years be screened annually for cigarette use and counseled to avoid tobacco and other abusable substances.[6]

Because the role that practitioners play in smoking prevention is not fully understood,[7] findings from a cross-sectional survey of Connecticut pediatricians, family practitioners, and general dentists are reported here.

Methods

Early in 1992, pediatricians (n = 156), family practitioners (n = 261), and general dentists (n = 257) from across the state were sent a two-page questionnaire on smoking prevention counseling of adolescent patients (10 through 18 years old). Random samples, accounting for roughly one third of practicing pediatricians and general dentists and two thirds of family physicians, were drawn from membership rosters provided by the respective state associations.

The initial mailing of 674 questionnaires yielded 354 (52%) responses. Six weeks later a follow-up request was sent to the 320 nonrespondents, producing an additional 89 replies for a total response rate of 66%. Pediatricians were somewhat more responsive to the initial mailing than either family practitioners or dentists, but overall responses were equivalent across groups (67%, 66%, and 64%, respectively). Initial and follow-up replies did not differ noticeably and were combined for analysis. Unfortunately, the characteristics of responders, nonresponders, and nonmembers of professional organizations could not be compared.

As a group, respondents were predominantly male (86%), never smokers (66%), and solo practitioners (55%) with substantial patient care experience (median experience was 14 years). Seven respondents (1.6%) reported being current smokers. Dentists, compared with physicians, were more likely to be solo practitioners (62% vs 51%, respectively) and more likely to have practiced more than 20 years (36% vs 23%, respectively). They were as likely as physicians to be male and to have a history of cigarette use.

Respondents were asked to estimate the proportions of their patients aged 10 through 12, 13 through 15, and 16 through 18 years who smoked. They were also asked to use selected descriptors ("always," "frequently," "occasionally," "seldom or never") to characterize how often they counseled young patients to avoid smoking and to indicate why they did not always counsel young patients. Counseling was not specifically defined and could have been interpreted by respondents as anything from a brief

Note. The percentages shown are percentages of respondents who answered the question about counseling patients in the indicated age group, not percentages of the total number of respondents.

TABLE 2—Perceived Barriers to Routine Counseling of Adolescents to Avoid Tobacco Use, by Practitioner Specialty

	No. Responding			
	Pediatricians (n = 105)	Family Physicians (n = 172)	General Dentists (n = 166)	Total (n = 443)
Counseling is generally ineffective in altering behavior of adolescents	6	15	27	48
Counseling is inconvenient in my practice setting	11	9	23	43
I don't feel qualified to counsel patients on this matter	0	0	21	21
It's difficult to know which of my patients are truly at risk	6	21	51	78
Compensation for wellness care is inadequate	3	8	7	18
Total no. (%) perceiving barriers*	26 (25%)	42 (24%)	90 (54%)	158 (36%)

*The number perceiving barriers does not equal the number of barriers reported because respondents could cite more than one barrier when answering the question. The percentage refers to the proportion of practitioners within a given specialty who perceived barrier(s) to counseling.

warning about tobacco use to more deliberate counseling sessions. Lastly, respondents were asked if they recorded tobacco use histories and/or episodes of tobacco counseling in their patients' medical records.

Results

Perceived Smoking Prevalence

Relatively few practitioners were familiar with cigarette use among their adolescent patients. Only one half of family practitioners (48%), few pediatricians (38%), and fewer dentists (26%) could estimate smoking prevalence within these age groups. Moreover, those making estimates tended to underestimate cigarette use; one half of respondents estimated the prevalence among 13- through 15-year-old patients to be less than 5% and one third estimated the prevalence among 16- through 18-year-olds to be less than 10%. (National estimates are that 8% to 11% of 13- through 15-year-olds and 16% of 16- through 18-year-olds use cigarettes frequently.[8])

Smoking Prevention Counseling Practices

Perhaps because practitioners do not perceive many adolescents as at risk, few counsel them about tobacco use (Table 1). Only 35% of the respondents reported "always" counseling 16- through 18-year-old patients, although another 30% indicated that counseling occurred "frequently." One half of the physicians, but fewer than 1 in 10 dentists (9%), reported "always" counseling this age group. Almost one third (31%) of dentists "seldom or never" counseled 16- through 18-year-olds about smoking.

Counseling decreased across all specialties for younger patients. One in five respondents (22%) "seldom or never" counseled 13- through 15-year-olds. Dentists were more likely than physicians to give this response (47% vs 7%, respectively). Only one quarter of the respondents (28%) indicated that they "always" counseled 13- through 15-year-olds, although a similar proportion of respondents described their counseling of this group as "frequent."

Only 38% of the respondents indicated that their 10- through 12-year-old patients were "frequently" counseled. Less than 20% of the respondents reported "always" counseling patients in this age group. Counseling by dentists was considerably below the level reported by physicians (i.e., those who reported "frequently" or "always" counseling patients in this age group were 14% and 48% of respondents, respectively).

Counseling practices of physicians and dentists were reexamined by sepa-

rately controlling for experience (≤ 14 years vs > 14 years), practice arrangement (solo vs group), smoking history (ever vs never), and sex. The patterns reported here were not affected by these procedures.

Barriers to Routine Counseling

Eighty-one respondents (51% of those who cited barriers to regular counseling) believed that "counseling is generally ineffective in altering behavior of adolescents"; an additional 78 respondents (49% of those who cited barriers) answered, "It's difficult to know which of my patients are truly at risk" (Table 2). Twenty-one dentists indicated "I don't feel qualified to counsel patients on this matter."

Record Keeping of Prevention Counseling

Most physicians (66%) routinely noted tobacco use by their adolescent patients in the patients' medical records, and many (45%) recorded counseling episodes as well. Dentists tended to record neither smoking histories (37% reported doing so) nor counseling (19%) in patients' records. (Both differences between physicians and dentists are significant at $P < .01$).

Discussion

Primary care providers are uniquely situated to help adolescents avoid experimentation with cigarettes. Providing information on the health effects of tobacco use along with incentives and skills to resist pressures to use tobacco can prevent some adolescents from becoming smokers.[9,10] Current practice guidelines recommend that prevention counseling be a regular part of health care for this population.[6] Unfortunately, active intervention by practitioners with adolescent patients is alarmingly low. These findings, which may be "best case" estimates because of a tendency among respondents to offer "socially approving" replies, indicate that counseling, especially for the youngest adolescents (10 through 12 years old), occurs infrequently. Dentists, in particular, are not likely to address the matter in their practice.

Uncertainty about how to incorporate prevention and disease screening within clinical activities[11,12] and how to communicate disease prevention messages effectively[13] contribute to the deficiencies noted above. Schools of medicine and dental medicine have special obligations to educate students, residents, and postgraduates about prevention counseling. Training must emphasize the successively younger ages at which adolescents are experimenting with tobacco. Instruction in prevention skills is needed early and often in physicians' and dentists' curriculums. All young persons are at risk for tobacco addiction and are suitable targets for prevention counseling. □

Preventing Firearm Injury among Children: Free Materials for Healthcare Professionals

On an average day, 14 children and teenagers die in unintentional and intentional gun incidents. The American Academy of Pediatrics, Dr C. Everett Koop, and the Center to Prevent Handgun Violence have created Steps to Prevent Firearm Injury (STOP), a program that provides materials for pediatric health professionals to use in counseling families on firearm injury prevention. The materials include information highlighting the danger of keeping a gun in the home and guidelines for safe home storage of guns and ammunition.

Pediatric health professionals may request a free kit containing 25 parent/patient brochures, 2 office posters, a monograph on background information, an audiotape with sample patient counseling sessions on gun safety, a counseling tip sheet, and suggestions for further reading.

To receive a kit, send your request to the Center to Prevent Handgun Violence, PO Box 425, Bladensburg, MD 20710-9974. For further information, contact Ricky O'Kane at the Center to Prevent Handgun Violence, tel (202) 289-7319.

An Increase in *Haemophilus influenzae* Type B Vaccination among Preschool-Aged Children in Inner-City Los Angeles, 1990 through 1992

Donnell P. Ewert, MPH, Suzanne Westman, MD, MPH, Bridget Ward, MS, RN, Nancie Bendaña, MS, RN, Ron Halbert, MD, MPH, Constance M. Vadheim, PhD, Joel I. Ward, MD, and Laurene Mascola, MD, MPH

ABSTRACT

Haemophilus influenzae type b (Hib) vaccination coverage and disease incidence were measured among preschool-aged children residing in inner-city Los Angeles. Among children 1.5 to 14 months of age, vaccination coverage of at least one dose increased from 0% in 1990 to 82% (95% confidence interval [CI] = 73%, 91%) in 1992. Among children 15 to 59 months old, vaccination coverage of at least one Hib dose administered at or after age 15 months increased from 35% (95% CI = 29%, 41%) in 1990 to 63% (95% CI = 56%, 70%) in 1992. Although Hib vaccination has reduced disease incidence in this population, greater use of vaccine can result in further reductions. (*Am J Public Health.* 1994;84:1154–1157)

Introduction

Before effective vaccines were widely administered, *Haemophilus influenzae* type b (Hib) was the leading cause of bacterial meningitis and an important cause of bacteremic infection in children less than 5 years of age. Invasive disease affected 1 in 200 children before the age of 5 years, causing death in 3% to 6% of cases and permanent sequelae in 20% to 30% of survivors.[1] Although the incidence was greatest in children less than 2 years old, effective Hib conjugate vaccines were not available for children as young as 18 months old until December 1987 and were not available for infants as young as 2 months of age until late 1990 (Table 1).[1,2]

The Immunization Demonstration Project, sponsored by the Centers for Disease Control and Prevention, was initiated during 1990 to improve vaccination coverage in a predominantly Latino-populated 53-census-tract area in inner-city Los Angeles. The project conducted annual community vaccination surveys from 1990 through 1992, which afforded an opportunity to examine changes in Hib vaccination coverage and disease incidence. Although precipitous declines of Hib disease have been documented within various populations,[2–7] no study, to our knowledge, has demonstrated both an increase in Hib vaccination coverage and a decline of Hib disease incidence within a geographic area.

Methods

The Immunization Demonstration Project established a walk-in immunization clinic at public comprehensive health center A, where no such clinic had previously existed. This new clinic administered 1139 Hib vaccine doses in 1990, 5660 doses in 1991, and 6294 doses in 1992. The project also increased the capacity of an already-established walk-in immunization clinic at public comprehensive health center B by increasing the nursing and clerical staff. Both health centers were located within the project catchment area.

The cluster survey methodology used extensively by the World Health Organization's Expanded Programme on Immunization was used to measure levels of Hib vaccination in preschool-aged children. This method has been used successfully in developing countries[8,9] and was recently adapted for use in urban areas of the United States.[10] During the three Immunization Demonstration Project surveys, 50 clusters were systematically selected from the 53-census-tract catchment area with probability proportionate to size. A random starting point was determined for each cluster by randomly selecting a city block and a residence on the block. Households were visited consecutively from the starting point, and all children from seven eligible households were included.

Household inclusion criteria were permanent residence of a child 6 weeks to 59 months of age and the presence of a respondent at least 16 years of age who was willing to participate. Possession of a written vaccination record was not required for inclusion in the survey but was required for inclusion in the analysis of

Editor's Note. See related editorial by Shelov (p 1066) in this issue.

Hib vaccination. A standard interview form was used to obtain family information and the vaccination history of each child. While the type of vaccine provider (public or private) was recorded during all three surveys, the specific clinic that administered each vaccine dose was recorded only during the 1992 survey. The type of Hib vaccine received by each child was not determined (Hib capsular polysaccharide vaccine [polyribosyl-ribitol-phosphate, PRP], Hib diphtheria toxoid conjugate vaccine [PRP-D], Hib diphtheria CRM197 protein conjugate vaccine [HbOC], or Hib meningoccocal protein conjugate vaccine [PRP-OMP]). Bilingual (English/Spanish) interviewers conducted interviews between 4 PM and 7 PM on weekdays and between 9 AM and 5 PM on weekends. The surveys took place between April 18 and June 26 of each year.

Active surveillance for cases of Hib disease was performed throughout Los Angeles County from January 1986 through December 1992, except for the period between July 1987 and June 1988 when surveillance was passive. Active surveillance consisted of calling all hospital infection control practitioners and laboratories in Los Angeles County once or twice a month to request case reports, auditing a 50% sample of hospital laboratories to identify positive Hib cultures, and reviewing medical records of pediatric patients discharged with any *International Classification of Diseases*, Ninth Revision,[11] diagnosis compatible with Hib disease. Passive surveillance consisted of telephone and written reports to the Los Angeles County Department of Health Services from hospital infection control practitioners, laboratories, and physicians.

An Hib case was defined as involving a child less than 5 years of age who had (1) clinical findings consistent with invasive Hib infection plus positive cultures from a normally sterile site; (2) clinical signs and symptoms consistent with epiglottitis with positive cultures from the pharynx, epiglottis, or blood; or (3) clinical findings consistent with invasive Hib infection plus Hib antigen in fluid from a normally sterile body site. Population data from the 1980 census, updated for births and deaths that occurred during the intervening years, were used to calculate rates.

Results

Only children with available written vaccination records were included in vaccination coverage estimates. Written records were available for 397 (79%) of 502 children in 1990, 395 (89%) of 445 children in 1991, and 397 (87%) of 458 children in 1992. The samples were 94% to 97% Latino and 2% to 6% African American; less than 1% of the children were members of other ethnic groups.

[a]From 1986–1989 mean incidence to 1992 incidence.

of Hib vaccine before age 15 months increased significantly from 1990 to 1991 and from 1991 to 1992 (Table 2). By 1992, large proportions of children had been vaccinated with second and third doses of Hib vaccine before 15 months of age; coverage increased with age until 12 months of age but declined thereafter (Figure 1). The proportion of children 15 to 59 months old who received one Hib dose at or after 15 months of age increased significantly from 1990 to 1991; this proportion also increased from 1991 to 1992 but to a lesser and nonsignificant extent (Table 2). Hib vaccination coverage was most complete among children 36 to 41 months of age during all 3 years (Figure 2).

Vaccination coverage of the one Hib dose given at or after 15 months of age increased significantly from 1990 to 1991 among clients of both public and private providers (Table 3). Although not statistically significant, vaccination coverage continued to increase from 1991 to 1992 among children obtaining vaccine from the health department, while coverage did not increase among children using private sources. Of the 332 children enrolled in the 1992 survey who had received at least one dose of Hib vaccine at any age, 59 (18%) and 43 (13%) received at least one dose from public comprehensive health centers A and B, respectively.

In the Immunization Demonstration Project catchment area, Hib disease in children less than 5 years of age declined 69% from the 1986 through 1989 mean incidence of 55.9 (per 100 000 person-years) to the 1992 incidence of 17.6. Incidence remained greatest among infants (Table 4) but declined 56% from the 1991 incidence of 129.1 to the 1992 incidence of 56.5. No children 24 through 59 months of age with Hib disease were reported in the project catchment area from February 1990 through December 1992.

Discussion

Dramatic improvement in Hib vaccination coverage among children less than 15 months of age occurred in this catchment area from 1990 to 1992. It is notable that Hib disease in preschool-aged children declined almost 70% from the 1986 through 1989 mean incidence to the 1992 incidence, even without active surveillance from July 1987 through June 1988, which was part of the baseline time period. The incidence of Hib disease in infants began to decrease before the introduction of infant vaccines in 1990, a result of vaccinating older children and reducing oropharyngeal carriage.[12] However, the precipitous decline in incidence among infants occurred during 1992, after infant vaccine was licensed. Although

vaccination against Hib disease among infants has increased rapidly, Hib vaccination coverage during the first year of life was still less complete during 1992 than coverage of infant doses of diphtheria–tetanus–pertussis (DTP) vaccine and oral polio vaccine (OPV) (Immunization Demonstration Project, unpublished data, 1992). Since incidence can be reduced further in infants by more timely and complete vaccination, improvement in Hib vaccination coverage during the first year of life should continue to be the main focus of public health interventions against Hib disease.

Vaccination coverage in the Immunization Demonstration Project catchment area increased significantly from 1990 to 1991 among children 15 to 59 months old. This increase, which probably resulted from more widespread use of Hib vaccine by providers, raised coverage to the level commonly seen with the fourth dose of DTP and the third dose of OPV. The small improvement in coverage from 1991 to 1992, especially among children vaccinated in the private sector, suggests that further improvement in coverage of the one Hib dose received at or after 15 months of age may be as difficult as improving coverage of other vaccine doses administered during the second year of life.

There were several limitations to this study. First, since the type of Hib vaccine received was not recorded during data collection and only three doses of PRP-OMP are required (with the third dose given at age 12 months), a small number of PRP-OMP final doses may have been misclassified as third doses in the 1992 survey. Second, since the data were analyzed by age group for different doses and children were not evenly distributed by age across all clusters, some clusters had more children represented than other clusters for the estimates of infant coverage, while the representation was opposite for the coverage estimate among older children. This unequal weighting may have introduced some unknown bias into the coverage estimates. Third, modifying the Expanded Programme on Immunization methodology to include seven households, instead of seven children, may have resulted in oversampling of households with more than one preschooler. Fourth, by attempting to limit recall bias by excluding from the analysis the 10% to 20% of children without written vaccination records, vaccination coverage may have been overestimated since respondents for children without records reported lower vaccination levels. This overestimation was probably very small because only small portions of the samples were excluded, and parents of children without written records tend to underestimate the number of doses previously received.[13] Finally, if persons not at home during the survey hours were different from those at home, some unknown selection bias may have been introduced into the coverage estimates. □

Acknowledgments

This study was supported in part by Centers for Disease Control and Prevention grant 666/CCU 901919-02, National Institutes of Health grant R01-AI-31580, and grants from Connaught Laboratories Inc, Merieux Institute Inc, and Merck Sharp & Dohme.

We wish to thank Leslie Hemenway, Eileen Eriksen, and Lawrence Valle of the Hib Surveillance Project for their assistance with active surveillance and Hector Bedoya, Patricia Luppi, and Arturo Picazo from the Immunization Demonstration Project for their assistance with the cluster surveys.

Using a Geographic Information System to Understand Child Pedestrian Injury

Mary Braddock, MD, MPH, Garry Lapidus, PA-C, MPH, Ellen Cromley, PhD, Robert Cromley, PhD, Georgine Burke, PhD, and Leonard Banco, MD

ABSTRACT

Data from police accident reports involving pedestrians less than 20 years of age in Hartford, Conn, during 1988 through 1990 were abstracted and entered into a geographic information system. Two high-frequency collision areas were identified and compared. There were 374 child pedestrians involved in collisions (a rate of 28 per 10 000). Two high-occurrence areas accounted for 30% of collisions. Collisions in one of these areas were more likely to involve younger children (8.1 vs 10.2 years of age) and to occur in the late afternoon, and occurred closer to the child's residence, than collisions in the other area. The geographic information system is a useful tool in the study of child pedestrian collisions. (*Am J Public Health.* 1994;84:1158–1161)

Introduction

Mapping disease events is a traditional approach to public health research.[1–7] However, point maps are an inefficient way of providing information for the development, implementation, and evaluation of public health programs.[8]

Geographic information systems allow management, analysis, and reporting of thematic data (demographics, health status indicators) within their geographic context (locations, boundaries).[9] Because many injuries have a strong geographic component, they are well suited to geographic information system analysis.[10-18] The purpose of this study was to demonstrate the usefulness of a geographic information system in examining child pedestrian collisions in Hartford, Conn.

Methods

All motor vehicle collisions reported to the Hartford police department between January 1, 1988, and December 31, 1990, involving pedestrians under 20 years of age were examined. Copies of police accident reports were obtained from the Connecticut Department of Transportation, and the following information was abstracted: date and time of collision, collision location, environmental conditions, vehicle type, pedestrian/vehicle maneuvers, contributing factors, pedestrian/driver age and sex, pedestrian place of residence, and injury severity.

A commercial geographic information system, TransCad,[19] was used to code the site of collision and pedestrian residence by address-matching these sites with the 1990 US Census TIGER/Line files for Hartford County.[20] Distances from collision sites to pedestrian residences were computed. The geographic information system produced point maps of collision and pedestrian residential locations.

Two areas of high collision density were identified for analysis. Descriptive, univariate statistics for collision, driver, and pedestrian characteristics were calculated. Because the data include the universe of all collisions during 1988 through 1990, inferential statistical procedures were not performed. Population data used to calculate rates were obtained from the 1990 census.[21]

Results

Between January 1, 1988, and December 31, 1990, there were 358 child pedestrian collisions in Hartford. These collisions occurred uniformly throughout the study period and involved 382 vehicles and 374 child pedestrians, resulting in an annual age-specific collision rate of 28 per 10 000 persons.

A point map of child pedestrian collision locations reveals that the collisions were distributed in a nonuniform manner with several high-frequency areas (Figure 1). Figure 2 selectively illustrates two high-frequency collision areas that accounted for 30% of all collisions. The Albany Avenue area is a 1.4 × 0.8 km (0.9 × 0.5 mile) section along Albany Avenue, a major commuting artery carrying an average traffic volume of 10 000 to 25 000 motor vehicles per day. The Park Street area is a 1.3 × 0.5 km (0.8 × 0.3 mile) section of a collector road carrying an average traffic volume of 3000 to 10 000 vehicles per day.[22] Both neighborhoods are densely populated with two- to three-story buildings of mixed residential/commercial land use.

Mary Braddock, Garry Lapidus, Georgine Burke, and Leonard Banco are with the Connecticut Childhood Injury Prevention Center, Hartford. Mary Braddock is also with St. Paul's Children's Hospital, St. Paul, Minn. Garry Lapidus, Georgine Burke, and Leonard Banco are also with the Department of Pediatrics, Hartford Hospital, and the University of Connecticut, Farmington. Ellen Cromley and Robert Cromley are with the Department of Geography, University of Connecticut, Storrs.

This paper was accepted February 15, 1994.

FIGURE 1—Child pedestrian–motor vehicle collision sites: Hartford, Conn, 1988 through 1990.

FIGURE 2—Albany Avenue (+) and Park Street (open circles) area collision sites, 1988 through 1990.

Sixty-nine collisions occurred in the Albany Avenue area, and 38 collisions occurred within the Park Street area. Figure 3 illustrates the location of the residences of children involved in pedestrian collisions in the two areas.

The characteristics of the two collision areas are compared in Table 1. In comparison with collisions in the Albany Avenue area, a greater proportion of those in the Park Street area occurred in the hours after school dismissal (61% vs 46%), on weekends (29% vs 20%), and during the summer (32% vs 17%). Children struck in the Albany Avenue area were older (mean ± SD = 10.2 ± 5 vs 8.1 ± 5 years) and more likely to be seriously or fatally injured (32% vs 13%) than those struck in the Park Street area. Driver error was more often a factor in the collisions occurring in the Albany Avenue area (29% vs 18%). Collisions in the Albany Avenue area also occurred at a greater (mean ± SD) distance from the child's place of residence (0.62 ± 0.8 vs 0.43 ± 0.8 km [0.39 ± 0.5 vs 0.27 ± 0.5 miles]). Collisions in the Park Street area more often occurred at intersections without a traffic signal (30% vs 14%). Collisions in both areas tended to occur on dry pavement and to involve male drivers in passenger cars. In general, characteristics of collisions in the Albany Avenue area were more similar to those elsewhere in the city.

Discussion

Pedestrian collisions are a leading cause of injury death and hospitalization among school-aged children.[12-14,23] Research shows that these collisions are not uniformly distributed within a city.[12-14] This study used a geographic information system to illustrate differences between two collision sites in Hartford, Conn.

Data were taken from police accident reports, which are known to underestimate the occurrence of nonroadway pedestrian collisions.[24,25] Nevertheless, police data include most serious traffic injuries to children and contain other valuable information concerning the collision event.[12-14,24-26]

This study found several differences between the two collision sites in Hartford. Of particular interest was the differing proximity of child residences to pedestrian collision sites. This type of information, which would not be easily accessible without geographic information system technology, has important implications for understanding and preventing child pedestrian collisions. A site-specific intervention suitable for the Albany Avenue area might include education aimed at school-aged children; environmental modifications designed to decrease traffic flow, improve intersection crossing times, and increase child pedestrian visibility; and improved police enforcement of vehicle speed laws and adherence to traffic signs. In the Park Street area, educational efforts directed at parents of preschoolers and school-

aged children, increased use of warning signs and crossing signals, and the development of off-street playground areas might be effective prevention strategies.

We are currently investigating other geographic features that may play an important role in child pedestrian collision etiology, such as schools, parks, playgrounds, and convenience stores. In conclusion, the ability of a geographic information system to illustrate spatial relationships between pedestrian collision sites and other city landmarks advances the study of pedestrian injuries. □

The Compliance of Licensed US Child Care Centers with National Health and Safety Performance Standards

David G. Addiss, MD, MPH, Jeffrey J. Sacks, MD, MPH, Marcie-jo Kresnow, MS, Joann O'Neil, BS, and George W. Ryan, PhD

ABSTRACT

The American Public Health Association and the American Academy of Pediatrics recently published health and safety guidelines for child care centers. A survey was conducted to determine the extent to which practices in US child care centers are reflective of these guidelines. Compliance with 16 guidelines ranged from 19.5% to 98.6%, varied considerably by state, and was not consistently associated with selected center characteristics. Prevention efforts should focus on practices for which compliance is low and on those that have the greatest disease- and injury-reducing potential. (*Am J Public Health.* 1994;84:1161–1164)

Introduction

In 1992, the American Public Health Association and the American Academy of Pediatrics published performance guidelines for the control of infectious diseases and injuries in US child care centers.[1] Adoption of these guidelines by providers will depend, in part, on whether compliance requires substantial or costly changes in child care practices, policies, or facilities. In November and December 1990, before the guidelines were published, we conducted a survey to determine the extent to which policies and practices in US child care centers were consistent with these guidelines.

Methods

A total of 2003 child care center directors were interviewed by telephone about their policies and practices for control and prevention of infectious diseases and injuries. This nationally representative sample was selected from lists of licensed child care centers in all 50 states, 14 local jurisdictions, and the District of Columbia. A minimum of 20 centers was randomly selected from each jurisdiction; the remainder of the sample was proportionately allocated according to the number of centers in each jurisdiction. Responses were weighted to obtain national estimates, and SUDAAN software[2] was used to compute 95% confidence inter-

TABLE 1—Percentage of Child Care Centers in Compliance with Recommended Practices and Policies to Control Infectious Diseases and Injuries

Performance Guidelines Reference	Practice or Policy Recommended by Guidelines	Centers Reporting Recommended Practice	
		%	95% CI
	Infectious disease practices		
HP 31	Staff use single-use disposable towels to dry hands	98.6	98.0, 99.1
HP 31	4-year-old children use paper towels to dry hands	98.2	97.6, 98.8
HP 79	Center has written policies for management of ill children	93.8	92.7, 94.9
FA 149	All diaper changing surfaces adjacent to a sink	76.1	73.8, 78.5
HP 25	Staff wash hands after every diaper change	73.7	71.2, 76.2
HP 24	Diaper changing surfaces sanitized after every diaper change	73.0	70.5, 75.5
HP 80	Director required to report a case of measles to a health agency	65.6	63.5, 67.8
HP 29	4-year-old children always wash hands after toileting	40.0	37.7, 42.4
ID 23f	Director required to report an outbreak of diarrhea (≥ 3 cases in children attending the same classroom) to a health agency	19.5	17.6, 31.3
	Injury control practices		
AD 70	Document all injuries serious enough to require first aid	89.8	88.4, 91.2
AD 34	Practice fire drills at least once a month	75.5	73.7, 77.3
AD 70	Injury reports filed in a separate log	48.5	46.2, 50.9
FA 251	Maximum height of playground equipment ≤ 165 cm (5.5 ft)	45.2	42.8, 47.6
App 33(o)	Poison control number posted by telephone	42.0	39.6, 44.4
FA 245	Surface under highest piece of playground equipment adequately resilient based on surface and on depth and height of equipment[a]	37.8	35.4, 40.2
ST 44	All staff certified in first aid	36.0	33.9, 38.2

Note. Figures are based on reports by child care center directors in a telephone interview. A copy of the questionnaire used in the interview is available from the authors. Performance references refer to recommendations included in the American Public Health Association/American Academy of Pediatrics guidelines.[1]

[a]The following were considered not in compliance: asphalt or concrete playground surfaces, equipment ≥ 120 cm (4 ft) above bare earth, equipment ≥ 240 cm (8 ft) above synthetic mat surfaces, equipment ≥ 120 cm (4 ft) above a loose fill surface (e.g., bark, wood chips, gravel, sand) ≤ 2.54 cm (1 in) deep, equipment ≥ 150–180 cm (5–6 ft) over loose fill ≤ 15.24 cm (6 in) deep, and equipment ≥ 300–360 cm (10–12 ft) above specific surfaces (details available on request from the authors).

vals. Logistic regression models were run to assess center characteristics associated with reported compliance with each of the 14 practices for which compliance was less than 95%. Each model included six center characteristics: number of children (< 40, 40 through 74, ≥ 75), average weekly fee per child (< $50, $50 through $69, ≥ $70), region of the country (South, Northeast, Midwest, West),[3] for-profit status, independent ownership (i.e., not part of a local, regional, or national chain), and affiliation with a religious institution that influenced center policies (no, yes). The Wald test was used to assess whether compliance with recommended practices was associated with any single characteristic after adjusting for the five other characteristics in the model.

Results

The response rate was 85%.[4] Child care centers cared for a median of 40 children full-time; the median weekly fee was $59 per child (range = $0 to $345). Forty-seven percent of centers were not-for-profit organizations, 74% were owned independently, and 31% were affiliated with a religious institution. Diapered children were accepted by 69% of centers.

Compliance with recommended practices varied (Table 1). Seventy-four percent of the directors of child care centers with diapered children reported that staff washed their hands after every diaper change. In contrast, 40% of all directors reported that 4-year-old children in their center always washed their hands after toileting. Directors in 94% of centers indicated that they had written policies specifying how mildly ill children should be managed; 66% stated that they were required to report a case of measles to a health agency or official, but only 20% stated that they were required to report an outbreak of diarrhea.

Almost 90% of directors indicated that they documented all injuries serious enough to require first aid, and 49% of centers filed injury reports in a separate log (Table 1). Emergency evacuation drills were practiced at least monthly by 76% of centers. Directors were asked to describe the surface under the highest piece of playground equipment; 38% of surfaces were considered to be adequately resilient. The poison control telephone number was reportedly posted by the telephone in 42% of centers.

Independent ownership, religious affiliation, and for-profit status of the child care center were associated with decreased compliance (odds ratio < 1) with some recommended practices (Table 2). The direction of association between recommended practices and other center characteristics, including fee and number of children, was inconsistent. Although region of the country was a significant predictor for more than half of the practices considered, the specific region that predicted compliance varied. We observed considerable state-to-state variability in performance of recommended practices within each region, and, even within individual states, reported levels of compliance were high for some practices and low for others (Figure 1).

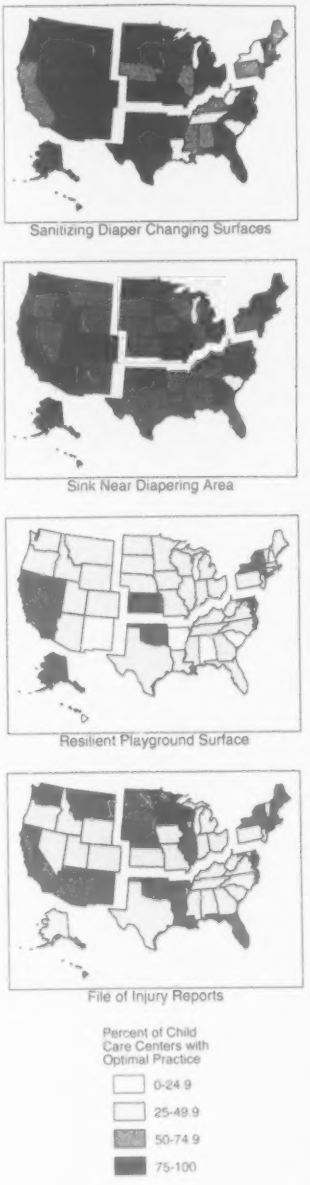
Discussion

Compliance with selected infectious disease and injury control practices recommended by the American Public Health Association and the American Academy of Pediatrics varies widely among licensed child care centers in the United States. Some recommended practices have been widely adopted, such as drying hands with single-use disposable towels, while others have generally not been implemented, such as reporting outbreaks of diarrhea to a state or local health agency. In general,

TABLE 2—Association between Child Care Center Characteristics and Compliance with Recommended Injury and Infectious Disease Policies and Practices

Recommended Practice	Region	Increasing Fee	Increasing No. of Children	Independent Ownership	Religiously Affiliated	For-Profit Status
Infectious diseases						
Written policy on ill children			↑ ↑			
Sink near diaper change areas		↑			↓ ↓	
Staff hand washing						
Sanitizing diaper changing surface	**	↑ ↑		↓ ↓		
Reporting measles	**	↑ ↑				
Child hand washing	*					↓
Reporting diarrhea outbreak	*			↓ ↓		
Injuries						
Documentation of injury	**		↑ ↑			↓ ↓
Fire drill practice	**					
Filing of injury reports					↓	
Playground equipment height	**		↓ ↓			
Posting poison control number	**					
Resilient playground surface		↑				
First aid training		↓	↓ ↓			

Note. Figures are based on reports by child care center directors in a telephone interview. The referents were as follows: southern region, fee < $50, < 40 children, nonindependent ownership, not affiliated with a religious institution, and not-for-profit status. The symbols ** and * indicate that compliance within one region significantly differed from that of other regions ($P < .01$ and $P < .05$, respectively). For dichotomous variables, ↑ ↑ and ↑ indicate an odds ratio > 1 compared with referent group ($P < .01$ and $P < .05$, respectively); ↓ ↓ and ↓ indicate an odds ratio < 1 compared with referent group ($P < .01$ and $P < .05$, respectively). For the continuous variables fee and number of children, ↑ ↑ and ↑ indicate a pattern of increasing odds ratios ($P < .01$ and $P < .05$, respectively), while ↓ ↓ and ↓ indicate a pattern of decreasing odds ratios ($P < .01$ and $P < .05$, respectively), as fee or number of children increases. For example, the proportion of directors reporting sinks near all diaper changing areas increased with increasing fee ($P < .05$) and was lower for religiously affiliated centers ($P < .01$).



Note. For each recommended practice, standard errors of state-specific point estimates exceeded 10% in as many as 15 states.

FIGURE 1—Percentage of child care centers complying with four selected infectious disease and injury control policies and practices, by state.

higher compliance was reported for infection control practices than for injury control practices, and a high degree of compliance was reported for procedures that could be easily observed or validated by licensing officials during inspections, such as having written policies for the care of ill children. However, performance was also low for some practices that could easily be verified, such as posting the poison control number by the telephone.

Implementation of some of the recommended policies and practices will require substantial changes in behavior or facilities. Performance of recommended practices was not consistently associated with specific child care center characteristics; thus, at a national level, these characteristics are unlikely to help identify high-risk centers in need of special interventions by licensing and public health officials. State-to-state variations among centers suggest that other factors such as differences in child care licensing, regulation, or enforcement[5,6]; staff training or availability of technical consultation[7]; or economic resources may be more strongly associated with performance of recommended practices.

Our study has several limitations. Actual practices could not be verified. Some interview questions may not have accurately measured compliance with a particular performance standard or may have addressed only one component of that standard. For example, the American Public Health Association/American Academy of Pediatrics guidelines recommend that handwashing sinks be "adjacent to diaper changing tables," whereas center directors were asked whether all diaper changing surfaces were "within an

arm's length (3 feet) of a sink for hand washing." The survey was conducted 1.5 years before the guidelines were published, but we believe it unlikely that practices changed significantly during this time. Finally, the precision of some state-specific estimates of reported practices was low; the standard error was greater than 10% for as many as 15 states.

Although considerable variation exists among child care centers, current infectious disease and injury control policies and practices in these facilities fall short of the American Public Health Association/American Academy of Pediatrics guidelines. Efforts should focus on improving policies and practices for which compliance is low and for which there is a demonstrated potential for reducing child care–related disease and injury. For example, only 38% of centers reported having adequately resilient surfaces on the playground; increasing this percentage could reduce the rate of injury.[8] Similarly, increased hand washing by children after toileting, currently estimated at only 40%, could contribute to reduced rates of diarrheal disease.[9] These national estimates provide baseline data for measuring the impact of efforts to reduce illness and injury in US child care centers. □

Acknowledgments

This research was presented, in part, at the 119th Annual Meeting of the American Public Health Association, November 1991, Atlanta, Ga.

Hearing Impairment among 10-Year-Old Children: Metropolitan Atlanta, 1985 through 1987

Carolyn D. Drews, PhD, Marshalyn Yeargin-Allsopp, MD, Catherine C. Murphy, MPH, and Pierre Decouflé, ScD

ABSTRACT

The prevalence of hearing impairment among 10-year-old children in metropolitan Atlanta between 1985 and 1987 was evaluated. Hearing-impaired children were identified by reviewing records at public schools and health and social service agencies. The prevalence was 1.1 per 1000 and was slightly higher among Blacks and boys than among Whites and girls. The most common known causes of hearing impairment were meningitis (0.3 per 1000), genetic and hereditary conditions (0.2 per 1000), and congenital rubella syndrome (0.1 per 1000). For 55% of the children, the etiology of the hearing loss could not be determined. Most (74%) of the children were diagnosed after the age of 2, suggesting that methods of early identification need to be improved. (*Am J Public Health.* 1994;84:1164–1166)

Introduction

Little information is available on the occurrence of childhood hearing impairment. In this paper we examine three aspects of childhood hearing impairment in metropolitan Atlanta during the years 1985 through 1987: its prevalence, its causes, and its association with other developmental disabilities.

Methods

The Metropolitan Atlanta Developmental Disabilities Study estimated the prevalence of five developmental disabilities among children who were born in 1975, 1976, or 1977 and who were living in metropolitan Atlanta when they were 10 years old.[1] This analysis focuses on hearing impairment, defined as an unaided bilateral pure tone hearing loss averaging at least 40 dB in the better ear at 500, 1000, and 2000 Hz.

Hearing-impaired children were identified by reviewing records of public schools, hospitals, and health and social service agencies, including all programs for the hearing-impaired sponsored by the state of Georgia. Data from all sources were reviewed to maximize ascertainment and to obtain complete information on

	Haemophilus influenzae Meningitis		Other Meningitis	
Age of Infection	No.	%	No.	%
0 to < 12 mo	8	61.5	4	57.1
12 to < 24 mo	4	30.8	1	14.3
24 to < 36 mo	1	7.7	1	14.3
≥ 36 mo	0	. . .	1	14.3

other disabilities and etiology. Although we did not include information from private schools, it is unlikely that we missed many cases because the children were enrolled in private schools.[1]

Etiology was defined as the underlying condition that led to hearing loss as documented on records from all ascertainment sources. Age at diagnosis was defined as the child's age the first time a hearing loss was documented in the available records.

Using data provided by the Georgia Office of Planning and Budget, we estimate that 89 534 10-year-old children lived in the study area during the years 1985 through 1987. Race was defined as White or Black because 96% of all 10-year-old children in Atlanta who were not White were Black, and 97% of the children identified as hearing-impaired were either White or Black.

Results

We identified 100 10-year-old hearing-impaired children (1.1 per 1000) (Table 1). The prevalence of hearing loss averaging at least 71 dB was 0.7 per 1000 children (95% confidence interval [CI] = 0.6, 0.9), and the prevalence of hearing loss averaging at least 90 dB was 0.5 per 1000 (95% CI = 0.4, 0.7).

Most of the children (88%) could be identified through the public school systems. Three children were enrolled in public school but were not included on the list provided to us, and nine were enrolled in state-supported schools for the hearing-impaired. Ninety-two percent of the children had received an audiogramwithin 3 years of ascertainment, and all but four cases had assessments after entering school. Overall, 93% of the assessments used to determine study eligiblity were by pure tone audiometry.

The etiology of the hearing loss was unknown for 55% of the children (Table 2). The prevalence of hearing impairment caused by *Haemophilus influenzae* meningitis was 0.2 per 1000 (95% CI = 0.1, 0.3). The rates of hearing impairment caused by other types of meningitis and by congenital rubella syndrome were each 0.1 per 1000 (95% CI = 0.03, 0.2).

Many cases of hearing impairment could be attributed to events, such as genetic conditions and congenital rubella syndrome, that occurred prenatally. In addition, *H influenzae* and other types of meningitis leading to hearing loss often occurred during infancy (Table 3). Only one case of hearing impairment was attributed to meningitis occurring in a child older than 36 months.

TABLE 2—Etiology of Hearing Impairment among 100 Hearing-Impaired 10-Year-Old Children Living in Metropolitan Atlanta, 1985 through 1987

	No.
Unknown	55
Genetic/hereditary[a]	13
Haemophilus influenzae meningitis	13
Other postnatal meningitis	7
Congenital rubella syndrome	7
Ototoxic drug	3
Cochlear dysplasia	1
Mastoiditis	1

[a]Includes one child with hearing impairment attributed to Soto syndrome and two children with hearing impairment attributed to neurofibromatosis. The other 10 cases were attributed to a genetic condition on the basis of a family history.

Although hearing impairment frequently developed before age 2, only 18 of the hearing-impaired children were known to have been diagnosed before the age of 2 years. Four of these were children in whom hearing impairment was attributed to a prenatal or genetic event, 1 was a child exposed to ototoxic drugs, 8 were children for whom the etiology of the hearing loss was unknown, and 5 were children who had had meningitis before the age of 2. Nearly half (n = 46) of the children were diagnosed before the age of 4 years and two thirds (n = 67) were diagnosed before the age of 6 years.

Nearly three quarters (n = 72) of the children with a hearing impairment did not have any of the other disabilities ascertained in the Metropolitan Atlanta Developmental Disabilities study (Table 4). Twenty-one hearing-impaired children also had mental retardation (0.2 per 1000, 95% CI = 0.1, 0.4; 10 children had mild mental retardation and 11 were severely retarded); 10 had epilepsy (0.1 per 1000, 95% CI = 0.05, 0.2); 9 had cerebral palsy (0.1 per 1000, 95% CI = 0.05, 0.2); and 3 were legally blind (0.03 per 1000, 95% CI = 0.01, 0.10).

Discussion

We observed a prevalence of childhood hearing impairment (1.1 per 1000 children) that is comparable to previously reported rates for developed countries (0.56 to 2.6 per 1000).[2-5] Ascertainment

TABLE 4—Number of Hearing-Impaired 10-Year-Old Children with Other Selected Disabilities, Metropolitan Atlanta, 1985 through 1987

Other Disabilities	No.
None	72
Mental retardation only	13

Cerebral palsy only	1
Blindness only	1
Mental retardation and cerebral palsy	1
Mental retardation and blindness	2
Cerebral palsy and epilepsy	2
Mental retardation, cerebral palsy, and epilepsy	5

methods and diagnostic differences may explain some of the variation in rates. We found that 57% of the children with a hearing impairment in Atlanta were boys, a proportion that is similar to that reported by other researchers.[2,4,6,7] The prevalence of hearing impairment was slightly higher among Black children than among White children; this finding needs confirmation in other studies.

In the present analysis, more than one quarter (n = 28) of the children with a hearing impairment had at least one of four other developmental disabilities. Other researchers have reported that 20% to 43% of children with a hearing impairment have another medical condition or disability.[4,7-9] It is difficult, however, to compare these proportions because of differences in the other conditions included and in ascertainment methods.

The prevalence of hearing impairment caused by congenital rubella infection has been reported to be as high as 0.5 per 1000 in children born before development of the rubella vaccine in 1970.[5,8,10] In contrast, we found the prevalence of hearing impairment resulting from congenital rubella syndrome to be 0.1 per 1000. The occurrence of hearing impairment resulting from this syndrome is likely to have decreased further among children born since 1977.[11,12]

Meningitis caused 20% of the cases of childhood hearing loss in this study. Previous researchers found that meningitis caused 3% to 13% of all childhood hearing impairments.[4,5,7,9,13] This difference may reflect changes in the occurrence of meningitis or hearing impairment or changes in the effectiveness of treatment for meningitis. Our findings confirm an earlier report that most cases of meningitis that lead to hearing impairments occur early in life,[7] and they correspond to what is known about the timing of *H influenzae* infections.[14] Because the incidence of *H influenzae* infection has already been reduced by the use of a vaccine,[15] the prevalence of childhood hearing impairment may be reduced by vaccinating infants as young as 2 months for *H influenzae*.[14,16]

The etiology of the hearing impairment could not be determined for a larger proportion of children in this study than has been reported in most other studies (i.e., 25%–48%).[5,7,8,13,17-19] This difference could reflect limitations in our method for determining etiology or differences in the definition of what constitutes a known etiology.

As has been found in previous studies, a large proportion of our cases of childhood hearing impairment, even those that developed prenatally or in infancy, were not diagnosed within the first 2 years of the child's life.[7,20-22] This finding does not appear to be an artifact of our ascertainment methods or of our inclusion of children born outside the study area, since the finding was not substantially altered when we limited our analysis to children born in the study area. These results are disturbing because of the importance of early intervention in the development of social skills and language.

Our data suggest that the development of rubella vaccination programs has already reduced the occurrence of hearing impairment and that vaccinating young infants against *H influenzae* may further reduce its occurrence. However, our data also suggest that many cases of childhood hearing impairment are not preventable, given current knowledge, because the etiology is either genetic or unknown. Thus, efforts need to be directed toward earlier identification and intervention. □

Socioeconomic Factors and Height of Preschool Children in the Czech Republic

Martin Bobák, MD, MSc, Bohumír Kříž, MD, PhD, David A. Leon, PhD, Jana Dáňová, MD, and Michael Marmot, FFPHM, PhD

ABSTRACT

The effect of socioeconomic factors on growth was investigated among 2275 children 3 to 6 years old attending nurseries in the Czech Republic. Measured heights of children were converted into height-for-age *z* scores. After adjustment for birthweight, parental height, and other socioeconomic variables, only mother's education was independently and significantly associated with children's height; adjusted differences in *z* scores between children of secondary- and university-educated mothers and children of mothers with only primary education were 0.12 and 0.31, respectively. This is equivalent to 0.5 and 1.5 cm, respectively, for children 5 years old. (*Am J Public Health.* 1994;84:1167–1170)

Introduction

Growth in childhood is considered to be a sensitive indicator of children's health.[1] It is susceptible to environmental factors and is thus useful for monitoring the effect of such factors on children.[2–6] Height in childhood is a good predictor of height in adulthood,[7] and adult height has been associated with mortality from a range of causes.[6,8]

Differences in children's height, which persist into adulthood,[9] have been reported between groups characterized by a wide range of socioeconomic factors such as social class based on parental occupation,[10–13] employment status,[5] family size and birth order,[3,5,10,12,14] parental education,[5,13] parental occupation,[5] and homelessness.[15] Because of the close correlation between education and other socioeconomic factors, previous attempts to estimate the independent effect of education have been inconclusive.[12,16]

Little is known of the magnitude of the effect of socioeconomic circumstances on health in the former socialist countries of central and eastern Europe. This analysis was conducted with three objectives: (1) to explore whether socioeconomic differences exist in growth impairment in the Czech Republic, (2) to investigate whether these differences are independent of parental height and birthweight, and (3) to determine which of the socioeconomic factors is most important.

Subjects and Methods

Preschool children 3 to 6 years of age attending 21 nurseries in five towns of the Czech Republic (Beroun, Most, Prague 3 district, Pribram, and Strakonice) were studied. All children registered in the nurseries in October 1992 were considered to be eligible for the study.

Parents were asked to complete a questionnaire on socioeconomic circumstances and life-style of the family, parents' height and weight, and children's health in the previous 12 months. Mothers and fathers were classified into three educational levels: primary, secondary, and university. A binary variable on crowding was calculated; families with more than one person per room were considered as living in crowded conditions. Information was also collected on car and weekend house ownership, whether the child lived with both parents, how often the child spent the weekend in the countryside, family size, birth order, birthweight, frequency of respiratory symptoms in the previous 12 months, maternal smoking (more than one cigarette a day), and history of breast-feeding.

Children's height and weight were measured in nurseries by centrally trained local public health workers (one to two in each town). A steel stadiometer, combined with a weighing device, was used in a standard fashion. Height was recorded to the nearest half centimeter. Because the height of young children depends critically on age, deviation from a growth standard was used instead of absolute measures. Epi-Info's anthropometric module[17] was used to convert individual anthropometric measurements to height-for-age *z* scores based on the US growth standards of the National Center for Health Statistics.[18] The height-for-age *z* score expresses, in terms of standard deviations, the extent to which the height of individual children differs from the value predicted by the growth standard

[a]Adjusted for birthweight and height of mother and father.
[b]Adjusted for biological and all socioeconomic variables.

The height-for-age *z* score was normally distributed. Differences in *z* scores between levels of explanatory variables were estimated with normal errors linear regression[19]; *z* scores, birthweight, and height of parents were modeled as continuous variables. Differences in *z* scores were adjusted first for "biological factors" (mother's and father's self-reported height and birthweight reported by the mother) and then for socioeconomic factors.

Results

Of the 2979 children registered in nurseries, 143 had never attended the nursery. Completed questionnaires were returned for 2366 children, and valid height was available for 2275 children (76% of those registered).

Table 1 describes the characteristics of our study population. The Czech children were almost half a standard

deviation taller than the American standards, the mean height-for-age z score being 0.49. Relatively more mothers had completed secondary school than fathers. About two thirds of families owned a car, and only 14% of children had two or more siblings. There was a positive association between mother's and father's education (data not shown).

Of the socioeconomic variables, education of parents, car ownership, crowding, number of siblings, and maternal smoking were significantly associated with height-for-age z score (see Table 2). Among the other variables, mother's and father's height and birthweight were most strongly related to z score; the multiple R^2 for these three variables was .20 (all P values less than .0001).

The effects of the various explanatory factors on height-for-age z score, adjusted for biological factors and then for all factors simultaneously, are shown in Table 2. After adjustment for birthweight and height of parents, maternal education and number of siblings retained their significant association with height-for-age z score. When all socioeconomic variables plus birthweight and parental height were included in one model, maternal education was the only socioeconomic variable that remained significantly associated with z score; children with primary-educated mothers were 0.12 and 0.31 standard deviations shorter than children with secondary- and university-educated mothers, respectively. This is equivalent to 0.5 and 1.5 cm, respectively, for 5-year-old children.

Discussion

Our study has several limitations. Only about 80% of all children in the Czech Republic attend nurseries,[14] and the five towns that were selected may not be fully representative of the whole country. While this should not affect the internal validity of the study, the effect of nonresponse is more difficult to assess. The cross-sectional design of the study is not optimal for establishing a causal association. All explanatory variables were self-reported, and a certain degree of misclassification cannot be excluded. This is particularly pertinent with respect to birthweight and height of mother and father. However, birthweight reported by mothers seems to agree well with medical records,[12] and, although adults tend to overestimate their height in a nonrandom fashion,[12,20,21] this bias is not independently related to social position.[21] Misclassification of this sort is unlikely to account for the strong association between maternal education and children's height.

Apart from birthweight and parental height, only maternal education was significantly related to children's growth in multiple regression, while the effect of other socioeconomic variables reflecting material conditions (crowding, car and weekend house ownership) disappeared.

The decline in the effect of maternal education after adjustment for parental height and birthweight suggests that some of the effect may be mediated through genetic and/or intrauterine factors. However, some of the effect must also be due to factors operating in childhood, because there remains a substantial difference in height by maternal education after adjustment for birthweight and parental height.

The mechanism in childhood through which maternal education affects growth is not clear. Our results do not support suggestions that breast-feeding, current maternal smoking,[22] or frequent disease[6,23] (Table 2) are related to height of children. Nutrition, however, is likely to play an important mediating role,[3,4,6,24,25] although only a few studies have investigated this question in developed countries.[26,27] Unfortunately, little is known about differences in nutrition by socioeconomic groups in the Czech population, although the expected differences would be reduced by the fact that children have their meals in nurseries. It has been suggested that maternal care and the nature of the mother–child relationship can affect growth.[26] However, our data shed no light on this issue. Further work is required to explain the central role of maternal education as distinct from other socioeconomic factors. □

The Demographic Distribution of US Drinking Patterns in 1990: Description and Trends from 1984

Lorraine T. Midanik, PhD, and Walter B. Clark, MA

ABSTRACT

Objectives. Since 1981, per capita consumption of alcohol (based on sales figures) has decreased in the United States. This study describes drinking patterns in the 1990 national alcohol survey by demographic correlates and assesses changes in drinking patterns from the 1984 survey.

Methods. Data were obtained from a national household probability sample within the 48 contiguous states; face-to-face interviews were conducted with 2058 adults. The instrument contained questions pertaining to the respondent's background, attitudes toward alcohol, and use of alcohol.

Results. The proportions of current drinkers; current drinkers of wine, beer, and liquor; weekly drinkers; and drinkers who reported having five or more drinks per occasion at least once a week were significantly lower in 1990 than in 1984. These changes remained significant when demographic characteristics were controlled by logistic regression. The findings held for Whites only; there were no significant trends for Blacks or Hispanics.

Conclusions. While there has been a downward turn in alcohol use in the United States, the correlates of alcohol use have not changed. How these shifts affect alcohol-related problems is an important area for future research. (*Am J Public Health.* 1994;84:1218–1222)

Introduction

National alcohol-use surveys in the United States, beginning with the Gallup poll in 1939, originally aimed at differentiating drinkers from nondrinkers. Later surveys focused on a wide array of drinking practices within the US household population. From these data, researchers have examined correlates of different patterns of drinking and assessed trends within certain subgroups.[1]

With the rise in per capita consumption indicated by sales data in the 1960s and 1970s, national surveys became important ways to monitor whether these increases were uniform throughout the population or within specific segments. Results were mixed. Johnson et al.[2] found in their analysis of seven national studies conducted from 1971 through 1976 that there was an overall increase in the proportion of heavier-drinking men and moderate-drinking women aged 35 through 49 years. Little change was detected in rates of abstention and rates of light, moderate, or heavy drinking in the US population in 1979,[3] and the 1984 national alcohol survey found few significant differences between 1967 and 1984.[4] An exception was a small increase in the number of male abstainers. Recently, Williams and Debakey[5] reported an increase in abstention and a decrease in heavier drinking between 1983 and 1988, based on National Health Interview Survey data.

Alcohol sales data through 1990 indicate that per capita consumption of alcohol fell from a high of 2.76 gallons per person aged 14 years or older in 1981 to 2.46 gallons in 1990—a change of nearly 11%. Liquor consumption fell from 1.02 to 0.78 gallons per person from 1981 to 1990, beer consumption fell from 1.39 to 1.34 gallons per person, and wine consumption fell from 0.35 to 0.33 gallons per person.[6] There are regional differences in apparent consumption of alcoholic beverages, but all census regions share in the downward trend in per capita consumption. However, useful as they are, per capita estimates obscure variations in drinking patterns and their correlates.

The purpose of this study is threefold. First, we will describe US drinking patterns in 1990 by demographic correlates. Second, we will compare the 1990 data on drinking patterns with comparable data from the 1984 survey to assess any changes in drinking patterns. Third, we will use multivariate analysis to determine whether the year of the survey is a significant predictor for any change in drinking patterns from 1984 to 1990 when demographic characteristics are controlled in the model.

Methods

Study Sample

The data were collected by the Institute for Survey Research of Temple University from a probability sample of 5970 housing units in 100 primary sampling units within the 48 contiguous states. Interviews were conducted from January through June 1990 with 2058 adults aged 18 years and older (70% response rate). The average length of an interview was 75 minutes, and respondents were paid $10.

The authors are with the Alcohol Research Group, California Pacific Medical Center Research Institute of San Francisco, Berkeley, Calif. Lorraine T. Midanik is also with the School of Social Welfare, University of California at Berkeley.

This paper was accepted November 18, 1993.

The 1984 national alcohol survey oversampled Black and Hispanic respondents within the 100 primary sampling units, and an additional 10 sampling units were selected from geographical areas with high proportions of Black and Hispanic residents.[1]

Weights were applied to both data sets to make them representative of the national household population in the United States during 1984 and 1990. First, a weight took into account demographic differences (age, sex, and region) and nonresponse rates. Second, an average design-effects weight based on selected alcohol use, alcohol-related problems, and demographic variables was derived, which takes into account clustering effects.[7] For the 1990 survey, the average design-effects weight was 1.79, which reduced the effective sample size from 2058 to 1150. In 1984, the average design-effects weight was considerably higher (4.24) because of the oversampling of Black and Hispanic respondents. Thus, the effective sample size was reduced from 5221 to 1228.

Dependent Variables

The description of patterns of alcohol use is no simple task, as Room's discussion makes clear.[8] Frequency of drinking, beverage type, quantity of alcohol per occasion, overall quantity, and volume per unit of time are all important measures for various purposes.

We used the following dichotomous measures of alcohol use during the 12 months preceding the interview: (1) current drinking (any alcoholic beverage use in the last year); (2) weekly drinking (any alcoholic beverage use at least weekly in the last year); current (3) wine, (4) beer, and (5) liquor drinking (any use of the beverage in the last year); and (6) five or more drinks (drinking five or more drinks on one occasion of any combination of alcoholic beverages weekly or more often during the last year).

The first two measures were based on an overall question about frequency of alcohol use: "How often do you *usually* have *any* kind of beverage *containing alcohol*, whether it is wine, beer, whiskey, or any other drink?" Measures 3 through 5 were based on similar questions about the frequency of use of each beverage type separately. Construction of the sixth measure was complex because there was no direct question that obtained this information. We used two questions, identical on both surveys, to construct the five or more drinks variable: "How often do you usually have wine or wine coolers?" and "Think of all the times you have had wine or wine coolers recently. When you drink wine, how often do you have as many as five or more glasses?" Parallel questions on beer and liquor were asked separately. (Details on the construction of this measure are available from the authors.)

TABLE 1—US Drinking Patterns: Percentages of 1984 and 1990 Survey Respondents Reporting Drinking Behaviors

	1984 (n = 5221)	1990 (n = 2058)	x^2
Current drinking	69.6	65.0	5.54*
Current wine drinking	51.2	43.6	13.95**
Current beer drinking	51.5	45.3	9.35***
Current liquor drinking	51.8	43.5	16.46**
Weekly drinking	35.9	29.0	13.03**
Having 5+ drinks on one occasion at least weekly	6.2	3.9	6.49**

Note. Percentages are based on weighted sample sizes (effective n's of 1228 for the 1984 survey and 1150 for the 1990 survey).
*$P < .05$; **$P < .01$; ***$P < .001$.

Independent Variables

Eleven independent variables were used to describe the subgroups of the population: gender, age, marital status, ethnicity, income, employment status, religion, importance of religion, education, urbanicity, and region.

Analysis

Descriptive comparisons between surveys were made by using a two-tailed difference-of-proportions test for each of the six dependent variables and for comparing proportions between the two surveys within each subgroup of the independent variables. We merged the two data sets and ran logistic regressions on each dichotomous dependent variable to test whether the year of the survey was a significant predictor when the effects of differences in demographic characteristics in these two surveys were controlled.

Results

1990 Cross-Sectional Data

About one third of adults reported no use of alcoholic beverages in the year preceding the survey (Table 1)—although the rate of abstention may be increasing, as will be noted below. Approximately 40% of adults reported drinking each of the three types of beverages in the last year. Just under one third of adults reported current use of any kind of alcoholic beverage as often as once a week, and a small proportion (3.9%) reported that they drank five or more drinks on one occasion at least as often as once a week.

Table 2 presents data on the use of any alcoholic beverage by demographic subgroups. Gender, as usual, was quite strongly associated with alcohol use. A statistically significantly lower proportion of women were current drinkers, weekly drinkers, or consumers of five or more drinks per occasion at least weekly. As in past surveys, age was negatively and significantly ($P < .05$) related to each of the measures of alcohol use and to the use of wine, beer, and distilled beverages considered separately.

Religious affiliation has been consistently associated with alcohol use in the United States. The religious groups here labeled conservative Protestants discourage the use of any alcoholic beverage by their members; other religious groups oppose only excessive use. Because of the small numbers, the comparisons presented here are of conservative Protestants vs all others. Significantly lower proportions of conservative Protestants reported current drinking, weekly drinking, and drinking five more drinks per occasion. Respondents who reported that religion was "very important" in their lives were less likely than others to drink by all measures of use.

We found no statistically significant differences in alcohol use among ethnic groups. This finding is of considerable interest because race and ethnicity have been significantly associated with alcohol use in past surveys, with Whites reporting higher rates of alcohol use on many measures. Whites in the 1990 survey did

(Continued)

report slightly higher rates of alcohol use than did Blacks or Hispanics, but the differences are not significant.

Marital status is a life-style indicator that, together with age, is related to patterns of socializing and to alcohol use. The never married, as a group, are younger than the married, and past surveys have often found that they report higher rates of alcohol use. Similarly, the 1990 data show significant differences between married and never-married respondents in weekly drinking and in the proportion reporting five or more drinks on one occasion at least weekly in the past 12 months.

Measures of household income, education, and employment status are positively associated with most measures of alcohol consumption, although small n's result in nonsignificant differences in many instances. The relationship of household income and the measures of alcohol use is the clearest of these three variables; those reporting household incomes above the median were significantly higher on all six alcohol use measures.

We also contrasted respondents in nonmetropolitan areas with those in metropolitan areas of less than 50 000 population and 50 000 or more. Respondents in large and small metropolitan areas did not differ significantly from each other, but there were significant differences ($P < .05$) between the metropolitan and nonmetropolitan groups on all measures except the five drinks per occasion measure.

Finally, we compared five census divisions of the United States. The Northeast was the "wettest" of these. Compared with the South, the Northeast had significantly higher rates on all consumption measures except the five drinks per occasion measure. The Northeast region's rates were higher than those of the remaining three regions as well; however, few of these differences were statistically significant.

Trends, 1984 through 1990

Table 1 shows data from both 1984 and 1990. In 1990 compared with 1984, there was a significantly lower proportion of current drinkers and a lower proportion of current drinkers of wine, beer, and liquor. There were also significantly fewer respondents reporting that they had drunk any alcoholic beverage as often as once a week in the preceding year, and relatively fewer who reported drinking five or more drinks per occasion as often as once a week.

Note. Percentages are based on weighted sample sizes (effective n's of 1228 for the 1984 survey and 1150 for the 1990 survey). Subgroup n's may not equal total because of missing data.

[a]Persons who reported having five or more drinks on one occasion at least once a week during the previous year.

[b]Defined as Protestant (no denomination mentioned), Lutheran, Presbyterian, Episcopalian, Unitarian/Universalist, Quaker, or Congregational.

[c]Defined as Baptist, Methodist, fundamentalist Protestant, Pentecostal, Assembly of God, Church of God, Nazarene, Holiness, Apostolic, Evangelical, Sanctified, Christian Church/Disciples of Christ, United Church of Christ, Christian Reformed, Jehovah's Witness, Seventh Day Adventist, Mormon/Latter Day Saints, Brethren, Spiritualist, Rastafarian, and Salvation Army.

[d]Northeast includes New England and Mid-Atlantic states; Midwest includes East North Central and West North Central states; Pacific includes only Pacific states; South includes South Atlantic, East South Central, and West South Central states; Mountain includes only Mountain states.

*$P < .05$.

Table 2 contains these same measures of alcohol consumption but shown within various categories of demographic characteristics. The same 1984 vs 1990 comparisons were made for the current use of wine, beer, and liquor considered separately (data not shown). In all, we made 336 comparisons, of which 124 were significant ($P < .05$); all these differences were in the direction of less alcohol use in 1990 than in 1984.

Table 2 contains proportions of current drinkers, weekly drinkers (of any alcoholic beverage in the past 12 months), and drinkers of 5 or more drinks on one occasion at least weekly during the past year. In almost all cases, the figures for 1990 are lower than those for 1984, although many differences fail to reach significance. Not shown here are data on current use of the three beverage types asked about in the two surveys. Generally speaking, the same patterns obtain for wine, for beer, and for liquor as obtain for any alcoholic drink. That is, there is a tendency for the 1990 figures to be lower than those for 1984, although the differences in smaller demographic categories are often too small to be statistically significant. As seen in Table 1, the percentage who reported drinking at least five alcoholic drinks at least as often as once a week in the last year was significantly lower in 1990 than in 1984. However, the data shown in Table 2 for persons who drank five or more drinks per occasion suggest that the figures for 1990 are often not significantly lower than those for 1984, even though the direction of differences is almost uniform.

The downturn in alcohol consumption between 1984 and 1990 was fairly general, but not uniformly so. White respondents reported significantly lower alcohol use by all measures in 1990 than in 1984, but no significant differences were found for Black or Hispanic respondents on any of the measures of alcohol use.

Gender differences in alcohol use, although still substantial, were smaller in 1990 than in 1984. For men, the 1990 figures on all six measures of alcohol use were significantly lower than those for 1984; for women, significantly lower figures in 1990 compared with 1984 were found only for alcohol use at least as often as once a week and any current use of beer or liquor.

As in previous surveys, older people reported lower rates of alcohol use than did younger people. Within age categories, the 1990 figures on alcohol use are generally lower than 1984 figures, but the differences often fail to reach statistical significance. The few significant differences between the two surveys occurred more often in the younger age categories (ages younger than 40 years).

Similarly, comparisons of marital status categories show lower rates of alcohol use in 1990 than in 1984, but few differences reach statistical significance. The never married reported more alcohol use than did members of other categories, but it was also among the never married that the rates of alcohol use on all six measures were lower in 1990 than in 1984.

As discussed in the description of the 1990 sample, conservative Protestants reported lower rates of alcohol use on almost all measures than did Jewish, Catholic, and liberal Protestant respondents. Among liberal Protestants, the 1990 rates were significantly lower than those for 1984 on all six measures of alcohol use. Catholics reported significantly lower rates of wine and liquor use in 1990 than in 1984 (data not shown). Respondents who said that religion was "very important" in their lives reported lower rates of alcohol use in 1990 than in 1984.

In general, lower rates of alcohol use were reported across all categories of education, family income, employment status, and urbanicity in 1990 than in 1984, but relatively few differences are statistically significant. One exception is in the rates for those employed full-time, for whom each measure of alcohol use was significantly lower in 1990 than in 1984.

A comparison of 1984 and 1990 data for regions indicates that rates of alcohol use were lower in 1990 than in 1984 except in the South. Of the other four census regions, only the Midwestern region was statistically significantly lower on all measures in 1990 than in 1984.

Given these shifts, is the downturn in alcohol consumption still apparent when the effects of changes in population characteristics are taken into account? To address this question, we used multivariate analyses that included simultaneous entry of all the independent variables shown in Table 2 for each alcohol measure.

The findings from the logistic regressions suggest that the apparent decline in alcohol use among US adults still holds when demographic characteristics of the

population are controlled. The data (not shown) indicate that for each of the six variables predicted, the year of the survey is a highly significant predictor, and that reduced odds of being in each predicted drinking category are associated with 1990 as compared with 1984. For instance, the odds of being a current drinker in 1990 were .696 compared with 1984. Similarly, the odds of being a weekly drinker were .617; of being a current wine drinker, .625; of being a current beer drinker, .703; and of being a liquor drinker, .613. Finally, the odds of reporting drinking five or more drinks on one occasion at least once a week were .515 in 1990 compared with 1984.

Because ethnicity has been an important factor in alcohol use in the United States, separate logistic regressions were run for White, Black, and Hispanic respondents. For Whites, year of survey was significant for all drinking measures except drinking five or more drinks on one occasion at least weekly. Year of survey was not significant for the Black or Hispanic groups for any of the alcohol use measures.

Discussion

The survey data comparing 1990 and 1984 indicate that rates of abstinence have increased in many sociodemographic categories and that some shifts in drinking patterns toward lighter drinking have also taken place. Rates of abstinence among US adults had remained more or less constant for about 50 years,[9] and yet the proportion of respondents who reported abstaining from each beverage or from all beverages seems to have increased in the short time between 1984 and 1990.

However, these data do not suggest that dramatic changes have taken place in the *correlates* of alcohol use since 1984. For instance, men and younger people of both sexes still include more drinkers and heavier drinkers than do women and older people, and regional differences in consumption patterns remain. The downturn in alcohol consumption that occurred among Whites did not extend to Black and Hispanic respondents. Since consumption as measured in 1984 was higher for Whites than for Black and Hispanic respondents, the result is a lessening of the differences between groups, and in 1990 no significant differences remained. Note that in the 1984 but not the 1990 national survey, Blacks and Hispanics were oversampled to permit detailed analyses of drinking patterns and problems in these groups.[10,11]

Will this downward trend in consumption continue? Some researchers have found reason to believe this is the case.[5,12] Room[12] has suggested that the climate of opinion that favored alcohol consumption, and which tolerated some level of alcohol-related problems, reached a periodic high point around 1980 or so and has begun a decline. He notes that a similar downward swing occurred in the years preceding Prohibition, and that this downturn was followed by an upward trend from 1980 to 1993. He argues that it takes about three generations to forget the troubles that accompany high consumption rates, after which consumption may trend upward. And it may take about the same time for rates of alcohol use and problems to increase to the point where popular sentiment supports measures intended to reduce consumption.

Williams et al.[5] add that the population as a whole is aging, and that age is negatively related to alcohol use. Data from the 1990 National Household Survey on Drug Abuse suggest that use of other drugs, including marijuana and cocaine, has declined at about the same time that alcohol use has declined.[13] Given that this trend is occurring, an important issue to consider is whether these changes will affect the prevalence of alcohol-related problems, and, if so, which ones. □

Drinking Water Mutagenicity and Gastrointestinal and Urinary Tract Cancers: An Ecological Study in Finland

Meri Koivusalo, MD, Jouni J. K. Jaakkola, MD, DSc, Terttu Vartiainen, PhD, Timo Hakulinen, ScD, Sakari Karjalainen, MD, Eero Pukkala, MA, and Jouko Tuomisto, MD, PhD

ABSTRACT

Objectives. **The purpose of this study was to investigate the relationship between exposure to mutagenic drinking water and cancers of the gastrointestinal and urinary tract.**

Methods. **Past exposure to drinking water mutagenicity was assessed in 56 Finnish municipalities for the years 1955 and 1970. The cases of bladder, kidney, stomach, colon, and rectum cancers were derived from two periods (1967 to 1976 and 1977 to 1986). Age, sex, social class, urban living, and time period were taken into account in the Poisson regression analysis.**

Results. **Statistically significant exposure-response association was observed between exposure and incidence of bladder, kidney, and stomach cancers. In an ordinary municipality using chlorinated surface water, this exposure would indicate a relative risk of 1.2 for bladder cancer and of 1.2 to 1.4 for kidney cancer compared with municipalities where nonmutagenic drinking water was consumed.**

Conclusions. **The acidic mutagenic compounds present in drinking water may play a role in the etiology of kidney and bladder cancers, but, because the results are based on aggregate data, they should be interpreted with caution. (*Am J Public Health.* 1994;84:1223–1228)**

Introduction

The carcinogenic and mutagenic compounds found in chlorinated drinking water have raised concern over the potential long-term health effects of water chlorination and chlorination by-products.[1–3] Epidemiological studies have suggested an association between chlorinated drinking water and cancers of the urinary and gastrointestinal tract, but the evidence of such a causal relationship has remained inconclusive.[4–6]

The production of chlorination by-products depends on raw water quality and chlorination practices. In epidemiological studies on water chlorination and cancer, the quantitative estimates of exposure are mainly based on the volatile fraction of organic material, which contains compounds such as trihalomethanes. Since most of the organic compounds in drinking water—including the mutagenic ones—are known to be nonvolatile[3] and also acidic,[7] the amount of trihalomethanes may not necessarily reflect the potential carcinogenicity of chlorination by-products found in drinking water.

So far, no epidemiological studies have been published on the association of exposure to mutagenic drinking water and the risk of cancer. Because of the high content of organic material—mainly humic substances—in raw waters, high levels of mutagenic activity have been observed in Finnish chlorinated drinking waters.[7] A major concern is 3-chloro-4-(dichloromethyl)-5-hydroxy-2(5H)-furanone (MX), which has been shown to be a very potent bacterial mutagen[8] and genotoxic compound in laboratory animals.[9] The concentration of MX correlates well with the degree of mutagenicity.[10] MX has also been found in drinking waters in the United States,[11] Great Britain,[12] and Japan.[13] Thus, the purpose of this study was to investigate the relationship between exposure to mutagenic drinking water and risk of cancers of the gastrointestinal and urinary tract.

Subjects and Methods

It was important that the exposed and unexposed persons in the study be as comparable as possible with respect to other cancer risk factors. Thus, municipalities with large rural populations were excluded by limiting the study to those 63 Finnish municipalities administratively defined as cities or rural towns in 1950. To improve the validity of the study, municipalities with fewer than 2000 inhabitants, those with more than 80% of the population born outside the municipality, and those that had been merged with large rural municipalities were excluded from the study, thus reducing the number of municipalities to 56.

Numbers of new cancer cases were obtained from the population-based, na-

tionwide Finnish Cancer Registry. The multiple sources of information available guarantee an almost 100% coverage of all cancer cases in Finland.[14] The study focused on cancers of the stomach, colon, rectum, kidney, and bladder (*International Classification of Diseases*, 7th edition codes 151, 153, 154, 180, and 181, respectively). The observed number of cancer cases was obtained for each municipality by sex, age (5-year categories), and time period (1967 to 1976, 1977 to 1986). The expected number of cancer cases (5-year categories) was calculated for each stratum of sex, age, and period using the respective incidence rates for the total population of Finland. For the analysis, age was further pooled into four broad categories: 0 to 49, 50 to 64, 65 to 74, and from 75 years onward. In addition, age-adjusted incidence rates for all municipalities combined were calculated for both time periods (Table 1).

Assessment of Past Exposure to Mutagenic Drinking Water

The past exposure to drinking water mutagenicity was assessed with a method developed by Vartiainen et al.[16] for two time periods, using the index years 1955 and 1970 to adjust for time and exposure factors such as latency. Information on past routinely collected water quality parameters (e.g., permanganate consumption, pH, color, and ammonium and iron content), water treatment practices, and chemicals used (e.g., chlorine dose, pre- or postchlorination or both) in the municipal waterworks was collected from a questionnaire sent to the municipalities and from past surveys and archives of administrative authorities. The past drinking water mutagenicity was then assessed for both years on the basis of an equation[16] giving the estimated drinking water mutagenicity level in net revertants per liter (net rev/L). The drinking water mutagenicities for the equation were measured according to standard procedures[17] in the Ames test using *Salmonella typhimurium* bacterial tester strains TA100 and TA98 without enzymatic activation.

Water from different waterworks often gets mixed when used by consumers. In those municipalities with more than one waterworks, a mean was calculated weighted for the volumes of water supplied by the different waterworks. The exposure to drinking water mutagenicity was estimated to be zero for people living outside the public water supply system (private wells) as no mutagenicity has been observed in groundwaters.[16] For both years, 1955 and 1970, the population exposure (wm) was calculated by multiplying the proportion of the population within the municipal water supply system (w) by the estimated level of drinking water mutagenicity (m) (Table 2, Figure 1). For the statistical analysis, the level of mutagenicity was also categorized (no mutagenicity, less than 3000 net rev/L, and 3000+ net rev/L), and the average of mutagenicities in 1955 and 1970 was used. A more detailed evaluation and description of the past exposure assessment in terms of drinking water mutagenicity has been published elsewhere.[18]

Statistical Analysis

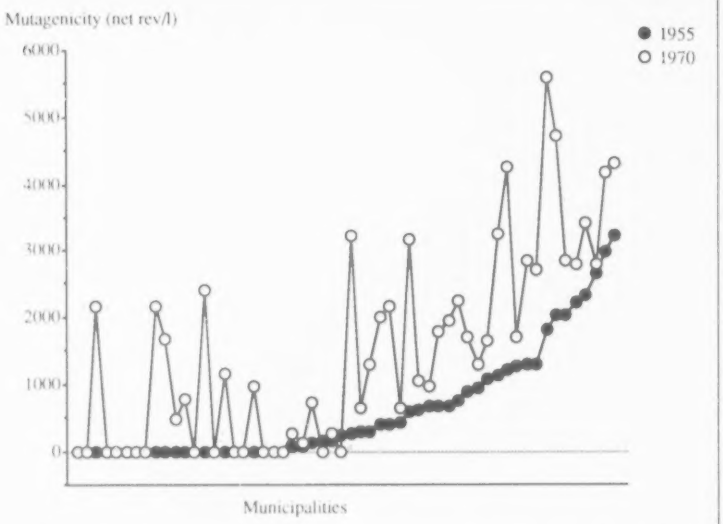
The observed numbers of cancer cases in each municipality were compared with the expected numbers of cancer cases based on the cancer incidence in the entire country in strata defined by sex, broad age group, and calendar period. The risk ratio (RR) between the observed and the corresponding expected number of cancer cases was modeled according to an additive relationship:

$$RR = \alpha + \gamma wm + \Sigma\theta_i s_i.$$

The baseline risk α was allowed to differ in strata defined by sex, age, calendar

period, and urban living. The parameter γ thus gives the change in risk ratio related to a unit of change in population exposure to mutagenicity (wm). In the control of confounding, the relative sizes of social classes in each municipality were used to describe life-style and smoking habits. The relative size of the two highest social classes out of four and the proportion of the lowest class in each municipality were derived from the 1970 census[19] and were used in the analysis as numerical variables (s_i, i = 1,2), with parameters θ_i specifying the relationship with social classes. The three largest cities in Finland, with their comparably more urban environments and life-styles, were grouped into a separate category in the analysis, and a categorical variable was created to adjust for a different base level of risk in these cities.

The statistical analysis was performed using GLIM[20] with an identity link function and a statistical model based on Poisson regression.[21] The effect of drinking water mutagenicity was studied as both a categorical and a numerical variable, and logarithmic transformations were also fitted. In the final analysis, the choice of the model with respect to mutagenicity was based on its ability to explain the variation in the data with fewest model parameters. This resulted in a linear model with a numerical variable for exposure to mutagenicity in the final analysis. Overdispersion was estimated to be of the order of 10%.[22] Adjusting for this would not have changed the confidence intervals (CIs) of the model parameters to any substantial extent. For purposes of illustration, the transformed coefficient, $1 + \gamma 3000$ net rev/L, was used to derive a risk ratio related to a typical mutagenicity exposure of 3000 net rev/L (Table 2). In further study of confounding, separate analyses were performed without the three largest cities, without eight municipalities that had 2% or more of the population working in the chemical industry,[23] and without six municipalities that had the highest levels of migration (an average annual in-migration of more than 8% from 1966 to 1970).[24] To focus the analysis on the exposure-response association and the quantity of the biologically active compounds in drinking water, the statistical analysis was also performed separately for those 34 municipalities in which the population was exposed to mutagenic drinking water. The proportions of cancer cases attributable to exposure were calculated[25] using the linear model and the average population exposure level of 1600 net rev/L in 1955 (Table 2).



Note. Exposures were estimated by multiplying the proportion of the population within the municipal water supply system by the mutagenicity level.

FIGURE 1—Estimated exposures to drinking water mutagenicity in the 56 municipalities in 1955 and 1970, arranged by the estimated exposures in 1955.

Results

Considering the population mutagenicity exposure as the only risk factor in the model, the risk ratios of cancers of the bladder, kidney, and colon were significantly higher than 1 (Table 3). In an average municipality with chlorinated surface water, the exposure to drinking water mutagenicity for those within the municipal water supply system was 2700 net rev/L in 1955 and 3300 net rev/L in 1970. Thus, in colon cancer, a risk ratio of 1.31 corresponded to an exposure of 3000 net rev/L, indicating a 10% unit increase for each addition of 1000 net rev/L, according to the linear exposure-response relationship used. After adjusting for the background variables (age, sex, time period, largest cities) and social class, the risk ratios diminished in kidney and colon cancers.

The risk of bladder cancer was 1.17-fold (95% CI = 1.03, 1.31) among exposed as compared with unexposed persons when adjusted for the potential confounders. The risk remained approximately the same when the analysis was restricted to the 34 municipalities with mutagenic drinking water. The adjusted risk ratio for kidney cancer was 1.08 (95% CI = 0.91, 1.24) in the total study population and 1.32 (95% CI = 1.11, 1.53) in the restricted analysis. The risk of stomach cancer was also slightly higher among the exposed, with an adjusted risk ratio of about 1.1. The adjusted risk of colon and rectum cancer among exposed persons did not differ from the corresponding risk for unexposed persons by more than could be expected by chance.

The exposure was assessed for 1955, and the cancer risk was calculated for 1967 to 1986 (Table 3). Taking into account cases diagnosed between 1977 and 1986 only, the adjusted risk ratios were approximately the same, with the exception of slightly higher risks in kidney cancer (RR = 1.16; 95% CI = 0.97, 1.36) (Table 4). Applying the average exposure from 1955 and 1970 and cases diagnosed between 1977 and 1986, the adjusted risk ratios for bladder cancer were lower than those given in Table 3 (RR = 1.05; 95% CI = 0.92, 1.19 for all municipalities). In contrast to bladder cancer, slightly higher risks were observed in stomach cancer (RR = 1.09; 95% CI = 1.02, 1.17 for all municipalities). The restricted analysis of

[a]The risk ratios for cancer cases in 1967–1986 are calculated corresponding to exposure to drinking water mutagenicity in 1955 for all municipalities (n = 56) and municipalities with mutagenic drinking water (n = 34).
[b]Within each type of cancer, the variables listed are those added to the previous model.

municipalities with mutagenic drinking water resulted in slightly higher risk ratios for bladder, kidney, and stomach cancers. For other cancers, the change of time and exposure periods led to no major differences from the risk ratios reported above.

The analyses performed after exclusion of the three largest cities and the municipalities with the highest migration levels did not change the observed risk estimates. In kidney cancer, slightly higher risk ratios were observed after exclusion of the municipalities with chemical industry (Table 4). Interaction between exposure and gender was statistically significant ($P < .05$) only in kidney and colon cancers. For colon cancer, the adjusted risk ratios corresponding to those in Table 3 were 1.14 (95% CI = 0.92, 1.36) for men and 1.01 (95% CI = 0.87, 1.16) for women. The interaction between age and exposure was statistically significant ($P < .05$) in kidney cancer, with the greatest risk ratio observed among the oldest age group (Table 4).

The exposure-response association may be converted into the proportion of cancer cases from 1967 to 1986 attributable to drinking water mutagenicity. When the adjusted relative risks from the restricted analysis of municipalities with mutagenic drinking water in Table 3 are used, the calculated attributable proportions would be 10% in bladder, 15% in kidney, and 5% in stomach cancer. The respective numbers of new cancer cases between 1967 and 1986 may be derived by applying these proportions to the numbers of cases reported in Table 1.

Discussion

The results indicate that, in a typical municipality using chlorinated surface water (3000 net rev/L), the relative risks would be about 1.2 for bladder cancer, 1.2 to 1.4 for kidney cancer, and 1.1 to 1.2 for stomach cancer as compared with those persons not using mutagenic drinking water. When the exposed population is large, the detection and estimation of even small risks is important from the public health point of view. In the present study, the existence of a method for assessing the past exposure to drinking water mutagenicity, an accurate system of cancer registration, and a large variation in drinking water mutagenicities made it possible to demonstrate small, yet statistically significant excess cancer risks associated with the assessed past exposure to mutagenic drinking water.

The observation of an increased risk of bladder cancer is consistent with results of earlier case-control studies on drinking water chlorination and cancer.[4–6,26] An association between the exposure to chlorinated water and the occurrence of gastrointestinal cancers has also been reported in epidemiological studies.[4–6,27] Such an association was not observed in rectum and colon cancers in our study. In kidney and colon cancers, the observed difference in risk estimates by sex could be explained by higher consumption of water by men. Confounding by gender-related life-styles and occupations or interaction with other gender-related exposures and biological factors may also be involved. The observation of substantially higher relative risks for kidney cancer in the oldest age group is in line with a longer latency time. The observed increased risks of kidney and bladder cancers are in line with the pharmacokinetics of the strong water mutagen MX.[28] The protein-bound MX[29] may be released in the kidney and therefore may induce higher concentrations there than in most other tissues.[28] Although, according to current knowledge, MX is the compound of major concern, chlorinated compounds other than MX may also have a carcinogenic effect.

Socioeconomic status has been shown to be associated with the incidence of several cancers in Finland, including cancers of the colon, rectum, and kidney.[30,31] In the present study, social class was determined by occupation. In earlier studies, it has been shown to be associated with diet and way of life.[32] Occupation has been shown to be associated with smoking, explaining a large part of the variation in lung cancer incidence.[33] Therefore, social class may be regarded as a suitable surrogate variable for life-style, diet, and smoking on the population level. After the municipalities with the highest proportions of the population working in the chemical industry were excluded, the risk estimates were higher in bladder and kidney cancers. This finding may be owing to the confounding effect of chemical exposures in these municipalities. The population density is greater and the life-style different in the three largest cities. After social class variables were included in the model, the risk estimates were similar in the analyses with or without the three largest cities, which

TABLE 4—Risk Ratios for a Typical 3000 net rev/L Exposure in 1955 for Kidney Cancer When Background Factors and Social Class Are Included in the Model, Shown by Time Period and Chosen Restrictions

	Cancer Cases in 1967–1986				Cancer Cases in 1977–1986			
	All		Mutagenic Water		All		Mutagenic Water

Note. RR = risk ratio, CI = confidence interval.

indicates that the confounding effect of urban living was taken into account. As the inclusion of social class in the multiple regression model may not fully adjust for life-style factors, the residual confounding from life-style factors such as smoking may not be totally excluded.

In a previous study of 86 drinking water samples, the correlation coefficient between the measured mutagenicity in TA100 Ames *S. typhimurium* tester strain and the modeled mutagenicity was 0.85.[16] Assessment of past exposure is based on historical observed raw water quality parameters and water treatment practices and therefore on the real historical situation, even though the actual historical mutagenicity may only be approximated. The methods for determining permanganate values of water samples have remained unchanged since the 1930s. In surface waterworks, the water quality data have been analyzed monthly; in ground waterworks they are analyzed usually once every four seasons. The approximation of historical mutagenicity was based on annual averages, derived from monthly measurements in surface waterworks. These values therefore represent potential seasonal variations.

The current understanding is that the mutagenic compounds in drinking waters are predominantly produced during water chlorination.[34] In an earlier survey, only one raw water source was shown to be mutagenic in the 1980s, and even in this case the mutagenicity of drinking water grew several times higher during water treatment.[16] Other exposures mediated by the water supply network, such as radioactive substances or asbestos from raw water or waterpipes, are unlikely,[35,36] and there is no evidence that these are related to drinking water mutagenicity. Until recently, consumption of bottled water and soft drinks has been very low in Finland, at least when compared with that in western and southern Europe and the United States.

The good coverage and quality of the Finnish Cancer Registry ensure the validity of the outcome assessment. Finland has a rather homogeneous population. During the 1960s, the direction of migration was from rural areas to towns, and therefore from areas of no or low exposure to high-exposure regions. In the 1970s and 1980s, migration between towns was also substantial. Confounding by migration would most probably diminish the estimated risks ratios.

Ecological studies are known to involve problems such as the ecological fallacy.[37] In the present study, the proportion of exposed persons was taken into account in each municipality, thus reducing the degree of ecological fallacy but not eliminating it, as the analysis was based on aggregate data. The fact that the expected rates were related to the whole country rather than to the chosen municipalities was taken into account by including in the model baseline risk parameters specific for sex, age, time period, and urban living. The Poisson distribution assumption of the number of observed cases enabled us to take into account the different sizes of the municipalities, and to study the proportion of persons exposed and the mutagenicity level of those exposed simultaneously in the analyses. The observed exposure-response association in the restricted analysis of municipalities with exposure to mutagenic drinking water indicated that the observed risk is more closely associated with the level of mutagenicity than with drinking water chlorination or mutagenicity as such.

Our findings suggest that the acidic mutagenic compounds present in chlorinated drinking water may play a role in the etiology of kidney, bladder, and possibly stomach cancer. Nevertheless, as the study was based on aggregate data, our results should be interpreted with caution. □

A National Study of Transitional Hospital Services in Mental Health

Robert A. Dorwart, MD, MPH, and Claudia W. Hoover, MA

ABSTRACT

Objectives. **Shifts in care for the seriously mentally ill from inpatient to community-based treatment have highlighted the importance of transitional care. Our objectives were to document the kinds and quantity of transitional services provided by psychiatric hospitals nationally and to assess the impact of hospital type (psychiatric vs general), ownership (public vs private), case mix, and revenue source on provision of these services.**

Methods. **A national sample of nonfederal inpatient mental health facilities (n = 915) was surveyed in 1988, and data were analyzed by using multiple regression.**

Results. **Half (46%) of the facilities surveyed provided patient follow-up of 1 week or less, and almost all (93%) conducted team review of discharge plans, but 74% provided no case management services. Hospital type was the most consistent predictor of transitional care, with psychiatric hospitals providing more of these services than general hospitals. Severity of illness, level of nonfederal funding, urbanicity, and teaching hospital affiliation were positively associated with provision of case management.**

Conclusions. **Transitional care services for mentally ill patients leaving the hospital were found to be uneven and often inadequate. Reasons for broad variation in services are discussed. (*Am J Public Health.* 1994;84:1229–1234)**

Introduction

One result of the deinstitutionalization of patients from public mental hospitals in the 1970s was the movement of many patients with severe and persistent psychiatric disorders into general hospitals, effectively mainstreaming the mentally ill into the acute medical care system.[1] Another result was the reorientation of the locus of treatment for less acutely ill patients from inpatient facilities to a myriad of community-based clinical and support services.[2] There is general consensus among clinical and policy researchers, as well as among service providers, that although initial efforts to make this transition were partially successful, they were also marked by failures, as evidenced by rising readmission rates of the mentally ill to hospitals and a significant number of severely mentally ill individuals among the growing population who were homeless.[3] These developments brought a recognition of the lack of horizontal and vertical integration of administrative and financial functions within the mental health care system and acknowledgment that availability of services had been mistakenly equated with access to those services. By the 1980s, there was an emphasis on introducing managed care and central mental health authorities, which were expected to improve continuity and appropriateness of treatment.[4,5] In the last decade there has also been a shift from a predominantly public responsibility for inpatient mental health care to an increase in the number of patients cared for in private psychiatric hospitals.[6]

The Problem of Continuity of Care

Changes in the delivery system from public to private providership and from specialty hospitals to general hospitals and community-based services have raised concerns about the accessibility and quality of mental health care, particularly for patients with chronic disorders.[7,8] In response, both policymakers and service providers have targeted the importance of continuity of care for both clinical and supportive services. The transition from inpatient to community-based care is a particularly important one for psychiatric patients because it is at this point in the treatment system that many patients fail to connect with posthospital caregivers and fail to establish meaningful ties to needed aftercare services.

Although providing continuity of care is considered a critical function in the successful treatment of the seriously mentally ill, little is known about the kind and quantity of such services available to psychiatric inpatients in the United States.[9,10] This study attempted to discover the nature and amount of transitional services available to the seriously mentally ill when they leave inpatient care to live in the community. In this article, we distinguish transitional services—those specifically designed to link inpatient and ambulatory care—from traditional aftercare services provided in community-based settings.

The Link between Continuity of Care and Clinical Outcome

Numerous studies have documented the importance of aftercare services in improving the quality of life and reducing clinical symptoms of former psychiatric inpatients. Despite methodological shortcomings in some studies, the overall weight of evidence suggests that recently discharged inpatients who receive some kind of aftercare (e.g., medications psychotherapeutic, occupational, or case management) will function better after leaving the hospital than those who do not.[11-13]

Although it has been shown that aftercare services have beneficial effects, getting patients to aftercare is a need that has been largely unmet. Myerson and Herman concluded from their review of aftercare studies that "bridging strategies" were the most important link to satisfactory aftercare.[14] Despite its importance, the transition to aftercare is fraught with geographic, interpersonal, temporal, and logistical obstacles.[12,15]

In recognition of these difficulties, model treatment programs, such as the Robert Wood Johnson nine-city Demonstration Program,[4] have been designed specifically to minimize the gaps in treatment and support that characterize the majority of transitions from hospital to community-based services. To do this, model programs provide centrally administered financial, social, and clinical services to the patient. In most local mental health care systems, however, such central administration is not currently in use. In these systems, continuity of care occurs only when a case manager system is in place. Although models of case management vary, the goal in each is to provide continuity of care between treatment settings and to assist in matching services to the needs of each client. Case management is widely regarded as the most effective way to maximize patients' gains.[16-18]

Despite this evidence, such services are scarce. A New York State study of discharge planning in psychiatric facilities found that a large percentage of inpatients were referred to mental health clinics (85%), but very few facilities offered case-management services.[19] According to this survey, public specialty hospitals tend to provide more adequate discharge planning than do general hospitals. Services offered included formal discharge planning, psychiatric appointments, day program referral, and monitoring of patient care for more than 6 months after discharge. Shortell et al.[20] surveyed not-for-profit and for-profit system-affiliated hospitals and found that not-for-profit hospitals offered a higher volume of alternatives to inpatient services, including more unprofitable services, than did for-profit hospitals. Clark and Fox demonstrated the cost-effectiveness of case-management services.[21]

Hypotheses

Based on previous research, we anticipated that two structural measures—hospital type (specialty or general) and ownership (private or public)—would influence provision of transitional services. We expected to find that psychiatric (specialty) hospitals would provide transitional care to a greater extent than general hospitals for several reasons. First, the case mix of specialty hospitals (especially public ones) tends to include more chronic and severely mentally ill patients.[20] These patients are more likely to require transitional care of greater intensity and duration than that required by acutely ill, short-term patients usually seen in the psychiatric wards of general hospitals. Second, administratively, it is often more feasible for specialty hospitals than for general hospital units to provide transitional care services; follow-up and transitional care can be time consuming for staff and are more easily organized when a high proportion of patients with psychiatric difficulties justifies the assignment of full-time staff for this purpose. We also anticipated that public facilities would provide more transitional services than would private ones. Ownership form has been shown to be related to institutional mission, which is, in turn, correlated with institutional behavior.[5] Public facilities are expected to see their mission as one primarily of stewardship rather than profitability, thus allowing administrators to make decisions about service mix and staffing based on patient needs.

We anticipated, too, that source of revenues might be related to the provision of transitional services. It has been noted previously that one way in which privatization has affected mental health care providers is that, regardless of ownership, almost all inpatient facilities receive revenue from a variety of sources: contracts with states and counties, Medicaid, Medicare, and private insurers. We expected that those facilities receiving a greater proportion of public revenues would provide the most transitional care. The diagnostic mix of patients treated would also be related, we thought, to transitional services. Patients with long-term chronic illness, such as schizophrenia, often have greater need for assistance in making the transition to outpatient or community-based facilities than do those with shorter-term difficulty, such as depression.

Methods

The National Mental Health Facilities Study,[22] conducted between October 1987 and 1988, was designed to address unanswered questions about the ongoing privatization of mental health services in the United States. The survey consisted of a 200-item questionnaire mailed to some 900 administrators of all nonfederal psychiatric hospitals in the United States, including community mental health agencies with inpatient units, and a 75% random sample of psychiatric units in nonfederal general hospitals. The overall response rate was 60%, ranging from 78% for public specialty hospitals to 38% for for-profit specialty hospitals. A comparison of our findings on revenue sources, case mix, and staffing practices of for-profit specialty hospitals with data from national surveys by the National Institute of Mental Health[23] and the National Association of Private Psychiatric Hospitals yielded overall consistency. A more detailed discussion of sample selection and response rate was published previously.[22]

Questions on the survey addressed a broad range of issues concerning hospital ownership status, referral sources, clinical services, patient characteristics including diagnostic mix and payer mix, staffing policies, and treatment monitoring policies. Additional information about area characteristics for each hospital, such as population density, was available from the Department of Commerce's Area Resource File.[24] Within this context, the National Mental Health Facilities Study examined the impact of hospital type (specialty vs general), hospital ownership (public vs private), hospital revenue sources, and patient diagnostic mix on the type and duration of transitional care given discharged inpatients.

Dependent Variables

Hospital administrators were asked about six different aspects of their facilities' transitional care practices. A hospital's services included those provided by hospital staff and those contracted through other providers with hospital-administered funds. First, they were asked how

often (on a scale of never, sometimes, often) primary responsibility for ensuring that patients receive aftercare (e.g., psychotherapy, occupational, or case-management services) rested with the hospital as compared with the patients themselves, private practitioners, and state and community agencies; second, whether their facility conducted team review of discharge plans; third, whether staff were exclusively assigned to patient follow-up; fourth, whether case-management services were provided; fifth, whether the average length of follow-up contact lasted 1 week, up to 1 month, up to 6 months, or more than 1 year; and sixth, which of six follow-up methods was the one most often used: (1) patient is given follow-up appointment; (2) patient is given staff help with referral; (3) patient is sent appointment reminder; (4) patient is telephoned by aftercare provider; (5) staff visits aftercare providers; and (6) staff visits patients' homes.

Independent Variables

Each hospital reported the legal form of ownership (public, private nonprofit, private for-profit) under which it operated, as well the type of psychiatric unit (general or specialty) and whether the unit was a teaching facility for medical interns and psychiatric residents.

Hospital administrators reported the percentage of total psychiatric patient care revenues from private insurers, Medicare, Medicaid, state and county contracts, and direct payment by patients. Administrators also reported the proportion, by diagnostic category, of inpatients treated in the last year. The percentage of patients diagnosed with schizophrenia was used as an indicator of long-term chronic illness and thus identified the hospitals with a high proportion of those patients most likely to need specific help in making the transition from inpatient care to community-based care (see Table 1).

Statistical Analysis

Several variables were used initially in regression analyses to control for hospital and community characteristics. Generally, the availability of resources of many kinds (including staff and level of staff training) is greater for larger hospitals and for those in more urban areas. To control for these influences, we included a measure of the percentage of the hospital service area population that is urban (Department of Commerce Area Resource File),[24] the average daily hospital psychiatric census, and the concentration

Note. Data in ordinal form were treated as continuous and analyzed by using multivariate least squares regression. For these data, beta coefficients with corresponding *t* statistics are presented. Categorical data were analyzed by using logistic regression. For these data, odds ratios have been computed based on regression coefficients. CI = confidence interval.

[a]Adjusted R^2 = .027.

[b]Adjusted R^2 = .091.

[c]Adjusted R^2 = .059.

[d]Sign indicates the direction of the relationship between dependent and independent variables.

*$P \leq .05$.

of psychiatrists. The size of the hospitals' service area (as defined by hospital administrators) was also included because facilities serving a very large geographic area (e.g., a state or region) were presumed to have difficulty providing as much transitional care as those serving smaller areas, regardless of patients' needs or revenue sources. Of these, average daily psychiatric census neared significance as a positive predictor of the provision of case management ($\beta = .0008$, $P = .09$); degree of urbanicity was significant as a positive predictor of hospital responsibility for aftercare ($\beta = .003$, $P = .017$). These two variables were included in further analyses.

Regression Analysis

Regression analyses were used to examine the impact of the independent variables described above on the provision of transitional care. Dependent variables measuring hospital responsibility for aftercare, length of follow-up, and intensity of follow-up are ordinal and were analyzed by using a multivariate least squares regression model. Logistic regression was used in the analysis of categorical variables: assignment of full-time staff to patient follow-up and the provision of case management. For these variables, odds ratios and 95% confidence intervals were calculated based on the regression coefficients. Because almost all facilities surveyed (93%) provided team review of patient discharge plans, this variable was not included in the bivariate or multivariate analyses.

An additional series of regression analyses was done excluding hospitals that reported "never" taking responsibility for ensuring aftercare. We were interested to see if once a hospital has made a commitment to ensuring aftercare, the pattern of factors influencing transitional care might be different from those affecting all hospitals, including those that report never taking responsibility (15% of the current sample). Interestingly, the results were virtually identical to those found for the entire sample.

Results

Descriptive Statistics

Table 2 presents a profile of the kind and quantity of transitional care services available in specialty and general hospitals. Case management, generally regarded as the most clinically effective form of transitional care, was provided by only 26% of respondents. Seventy-three percent reported follow-up of discharged patients for 1 month or less; only half (54%) reported follow-up of more than 1 week. To address overlap between hospitals that reported assigning staff exclusively to patient follow-up and those that reported providing case management, we did additional analyses. These showed that 35% of the sample provided neither case management nor full-time follow-up

staff; 40% had full-time follow-up staff but did not provide case management.

We found that almost all inpatient facilities surveyed (93%) conducted a team review of patients' discharge plans; however, there is a great deal of variation among hospitals in how discharge plans are carried out. Over half (59%) of the facilities had staff assigned exclusively to patient follow-up, but when asked how often the hospital (vs the patient or the physician) took responsibility for ensuring aftercare, 35% answered "sometimes" and 50% answered "often." When asked what method of follow-up was used most often, 78% reported that their hospital either set up initial aftercare appointments for patients or made a staff person available to help with a referral.

Regression

Hospital type (psychiatric vs general) was by far the strongest determinant of transitional care practices (Table 3). After controlling for case mix, among other factors, psychiatric hospitals reported taking more responsibility than did general hospital psychiatric units for ensuring that patients received aftercare ($\beta = -.223$, $P = .0003$). Psychiatric hospitals also provided follow-up for patients for a longer period ($\beta = -.705$, $P = .0001$), and used more intensive methods of follow-up ($\beta = -.693$, $P = .0001$). Specialty hospitals also were more likely to assign full-time staff to follow-up ($\beta = -.809$, $P = .0001$).

The provision of case management was not predicted by hospital type. It was, however, associated positively with severity of patient illness (percentage diagnosed as schizophrenic) ($\beta = .021$, $P = .0001$). The level of state mental health funding (other than Medicaid) ($\beta = .010$, $P = .0005$) was also a positive predictor and may be an index of severity of illness.

Duration of follow-up, although most strongly and positively associated with hospital type, was also negatively predicted by severity of illness ($\beta = -.005$, $P = .041$); that is, the greater the percentage of patients with schizophrenia in a facility, the shorter the average length of follow-up care provided. Offering residency training was positively related to four of the five transitional care indices: length of follow-up ($\beta = .182$, $P = .05$), hospital responsibility for ensuring aftercare ($\beta = .125$, $P = .054$), intensity of follow-up methods ($\beta = .232$, $P = .051$), and provision of case management ($\beta = .511$, $P = .006$). Level of funding from the state was negatively associated with level of hospital responsibility ($\beta = -.003$, $P = .03$).

Discussion

Not surprisingly, the type of hospital (specialty vs general) strongly influences how the institutions' managers perceive their role and affects their willingness to provide transitional care. Specialty hospitals tend to be freestanding hospitals located at a distance from other health care services; nonetheless, they often serve as referral centers and provide both acute and long-term services, as well as more specialized treatment programs. They usually are familiar with the range of services needed by their patients and work with the local service provider network. Although specialty hospitals have varied arrangements for providing ambulatory care, these facilities generally can provide ongoing treatment by their medical staffs or can help negotiate treatment by professionals in the community.

General hospitals, on the other hand, often view psychiatric services as a small part of their overall activity and usually treat only acute cases on relatively small (e.g., 20-bed) units. These units are part of a larger health care institution and community-care system that tends to be located in an urban area. General hospitals, therefore, often depend on local providers, such as community mental health centers, to take over postdischarge treatment. A notable exception to this trend is that 36% of facilities providing case management were nonprofit general hospitals. That could reflect the mainstreaming of the mentally ill to the acute medical care system. In all, these characteristics related to type predominate over ownership form per se in determining the hospital's behavior in providing transitional services. A special case is the public (state or county) mental hospital, which provides primarily intermediate and long-term care; after prolonged efforts by state governments to deinstitutionalize, many now place heavy emphasis on aftercare.

Case management generically may be viewed as the most intensive and assertive form of transitional or bridging services. We find that despite its importance in the eyes of family members, policymakers, managed care companies, and community mental health clinicians, this service is not very widely employed by hospitals—only 26% provide it, perhaps because it was a largely "non-reimbursable" service at the time of the study.

We found that transitional care was most likely to be available when the institution had a high number of patients who were severely ill (e.g., schizophrenia) and that there were strong correlations between this variable and the provision of case management. The reliance on relatively short-term follow-up and little patient contact to establish aftercare (Table 1) suggests that hospitals may recognize the need for follow-up but invest relatively few resources in doing it. Some of the factors associated with more efforts across the board to provide transitional care were the presence of state or county contracts for care, larger units, location in urban areas, and the presence of a residency training program. Apparently, teaching hospitals believe that providing transitional services is an important part of learning about clinical practice and they may allow additional staff time and incentives to follow patients as part of the training experience.

Conclusion

A national survey of mental health facilities found that transitional care services for mentally ill patients leaving the hospital were uneven and disappointing. Although there is widespread recognition of the need for providing transitional care services, there is also wide variability in the extent and willingness of hospitals to take responsibility for, and intensively implement, measures to ensure effective aftercare. Financial barriers appear to play a critical role. Hospitals that have a high proportion of patients with severe and persistent disorders and that receive nonfederal public funding for providing services are more likely than others to provide intensive follow-up, including case management. Although mental health care providers are increasingly influenced by pressures to economize, it is important that they remain aware of the need for structured, intensive, and specific transitional care interventions for all psychiatric patients. Private as well as public funding sources must recognize that appropriately designed incentives can play a role in encouraging institutions to provide this type of service. For public facilities, better transitional and aftercare services can reduce readmission rates and reduce costs. For private hospitals, changes in the financing of mental health care toward network and capitation arrangements under managed care systems should create new incentives to do likewise. To ensure adequate aftercare and case-management

services for severely mentally ill persons, national health care reform proposals should either provide for reimbursement (in the manner of current Medicaid programs) or else explicitly mandate responsibility for such services to state mental health authorities.[25]

Call for Abstracts for Injury Control Late-Breaker Session

The Injury Control and Emergency Health Services Section of the American Public Health Association will again feature a late-breaker session during the APHA annual meeting October 30 through November 3, 1994, in Washington, DC. The session will be held on Thursday, November 3, at 8:30 AM and will feature work completed within the last few months, after the deadline for consideration in the regular symposia of the meeting.

Abstracts of 250 words or fewer will be accepted by the section until *September 10, 1994*. No special form is required. Please send or fax the abstract, title of paper, author's name, address, telephone, and fax number to Rick Waxweiler, National Center for Injury Prevention and Control, Centers for Disease Control and Prevention, 4770 Buford Hwy, NE, Mail Stop F41, Chamblee, GA 30341; tel (404) 488-4031; fax (404) 488-4338. All submitters will be notified of decision by fax by September 24.

What Determines Mortality Risk in Male Former Cigarette Smokers?

ABSTRACT

Objectives. The purpose of this study was to examine what factors determine the mortality experience of male ex-cigarette smokers, those who no longer smoke at all and those who changed to pipe or cigar smoking.

Methods. A cohort study was undertaken with 18-year mortality data on 19 018 men.

Results. Ex-cigarette smokers had an intermediate mortality risk compared with never and current smokers. Ex-cigarette smokers who switched to pipe smoking had higher mortality than those who no longer smoked at all. The mortality rates for pipe and cigar smokers who were former cigarette smokers were higher than those for pipe or cigar smokers who had never smoked cigarettes. Ex-cigarette smokers who consumed more than 20 cigarettes per day for more than 20 years experienced increased mortality for both coronary heart disease and neoplasms, even after 30 years of cessation.

Conclusions. These results support the notion that an elevated mortality risk may be seen for ex-cigarette smokers, even after they have given up smoking for many years. Ex-cigarette smokers who change to a pipe have a greater mortality risk than those who no longer smoke at all. (*Am J Public Health.* 1994;84:1235–1242)

Introduction

The prevalence of smoking in many populations has been falling, in particular for men.[1] An ever-increasing proportion of the general population are former cigarette smokers who have either given up smoking or changed to a pipe or cigars. Many studies have reported reduced mortality for former smokers compared with smokers.[2–9] Whether former smokers ever reach the same levels of mortality risk as never smokers remains controversial.[10–12] The mortality risk of pipe or cigar smokers may also differ depending on a past history of cigarette smoking. These issues are of importance because they may provide some insight as to etiological mechanisms, enable better predictions of future trends in mortality, and provide the public with realistic expectations of the potential benefit, in terms of the reduced risk of mortality, that has been observed from stopping smoking.

The Whitehall Study previously reported no difference in risk of death from coronary heart disease between never smokers and ex-smokers after 5 years of follow-up.[13] We re-examined data from the Whitehall study after 18 years of follow-up. Our aims were to examine the mortality risk of former cigarette smokers compared with never smokers with particular reference to duration of smoking habit, number of cigarettes consumed, change in smoking habit, and time since giving up cigarettes. We also looked at the effect of changing from cigarettes to pipe or cigar smoking.

Subjects and Methods

In the Whitehall Study, 19 018 men aged 40–69 years from the British Civil Service were examined between 1967 and 1969. The main aim of the study was to examine what risk factors may be important in the etiology of coronary heart disease, as well as other chronic diseases.[14–16] In this cohort study, all exposure data were collected only at baseline with no subsequent reassessments.

If the subjects stated at baseline that they had never smoked any form of tobacco they were classified as never smokers. If they currently smoked cigarettes they were categorized as current cigarette smokers, irrespective of whether they also smoked a pipe or cigars. If subjects did not smoke cigarettes or any other form of tobacco at baseline but had ever smoked cigarettes, they were categorized as ex-cigarette smokers. Subjects who were ex-cigarette smokers but current pipe or cigar smokers were referred to as secondary pipe or cigar smokers. Subjects who had never smoked cigarettes but were current pipe or cigar smokers were referred to as primary pipe or cigar smokers. Current smokers of both pipe and cigars were excluded so that the effects of either pipe or cigar smoking individually could be examined. Three hundred ninety-five men who were former pipe or cigar smokers and no longer smoked at all were omitted from further analysis. For both current and ex-smokers, the age when they started to

TABLE 1—Distribution of Subjects, by Smoking Status

Smoking Status	No. (%) of Subjects
Total sample size	19 018
No data on smoking status	14
Both pipe and cigar smokers (excluded from analysis)	239
Ex–pipe or ex–cigar smokers (excluded from analysis)	395
Remaining sample size	18 370 (100)
Never smokers	3 105 (16.9)
Ex–cigarette smokers	4 833 (26.3)
Current cigarette smokers	7 921 (43.1)
Pipe smokers	1 748 (9.5)
Primary	492 (28.1)
Secondary	1 256 (71.9)
Cigar smokers	763 (4.2)
Primary	105 (13.8)
Secondary	658 (86.2)

smoke and the most they ever smoked regularly for as long as a year were ascertained. A small subsample of current cigarette smokers were later recruited into an intervention trial of smoking advice.[17]

Additional questions were asked about chest pain, respiratory symptoms, and civil service employment grade. Civil service employment grade is in four levels: administrators, professionals and executives, clerical, and "other" (mainly unskilled manual) grades. Administrators are the top grades, with the highest status and income in the civil service; the "other" grades are the lowest. For 873 subjects employed by the diplomatic service and the British Council, grades were not comparable to those for the rest of the sample. For analyses that involved grade, these subjects were kept as a separate group.

Clinical measurements included height, weight, blood pressure, forced expiratory volume in 1 second ($FEV_{1.0}$), forced vital capacity, and a limb lead electrocardiogram. An oral glucose tolerance test was administered (50 g) after an overnight fast, and a 2-hour capillary blood sample was drawn for the measurement of glucose and cholesterol concentrations.

Disease at entry was defined by any of the following: relative shortness of breath on level ground, probable or possible intermittent claudication,[18] past history of diabetes, heart or blood pressure trouble, unexplained weight loss over the preceding year, grade 1 or 2 angina according to the Rose angina questionnaire,[14] severe chest pain for over half an hour, and an abnormal resting electrocardiogram according to the following Minnesota code items: Q/QS waves (1.1–1.3); ST depressions (4.1–4.4); T-wave inversion or flattening (5.1–5.3); or left-bundle branch block (7.1). Full details of the procedures used were previously reported.[19]

Records from over 99% of subjects were flagged at the National Health Service Central Registry. Death certificates were coded according to the eighth revision of the *International Classification of Diseases* (ICD), and this almost-complete mortality follow-up to January 31, 1987, provides the basis for these analyses. Death was classified as being due to coronary heart disease (ICD codes 410–414); cardiovascular disease (ICD codes 390–458); neoplasm of trachea, bronchus, and lung (ICD code 162)—henceforth referred to as lung cancer—or any neoplasm (ICD codes 140–239); and respiratory disease (ICD codes 460–519). Neoplasms were also classified according to whether smoking is considered to play a role in their etiology.[2,5,20] The causes deemed to be smoking related are malignant neoplasms of the lip (ICD code 140), tongue (ICD code 141), mouth and pharynx (ICD codes 143–149), esophagus (ICD code 150), and pancreas (ICD code 157); respiratory system neoplasms (ICD codes 160–163) and urinary system neoplasms (ICD codes 188–189); and malignant neoplasms of unspecified site or secondary neoplasms (ICD codes 195–199). All other cancers were classified as not related to smoking.

The number of years since stopping smoking is often taken from the date of quitting up to the start of the study. That is reasonable when the period of follow-up is relatively short. With 18 years of follow-up, however, it will result in misclassification, as the number of years since stopping smoking for an ex-smoker actually increases over the follow-up period. To allow for this time dependence, the time data were analyzed by using the standard person-years approach.[21] For example, a subject aged 48 years at the start of the study who died after 13.5 years of follow-up would contribute 2 person-years to the age category 45–49 years, 5 person-years to the age categories of 50–54 and 55–59 years, and 1.5 person-years to the age category of 60–64 years. His death would be allocated to the 60–64-year category. If in fact this subject was an ex–cigarette smoker who had given up 3 years before the start of the study, then he would contribute 7 person-years to the 1–9 years since quitting cigarettes category and 6.5 person-years to the 10–19 years since quitting category, with his death being allocated to this latter category. Because of the size of the data set, person-years of observation during the 18-year follow-up were allocated on a year-by-year basis. For each year of follow-up, a new record was created consisting of each subject's current age together with baseline characteristics and length of follow-up during that year. For ex-smokers, the time since stopping smoking up to that year of follow-up was calculated as in the example above. This expanded data set was then used as the basis for all analyses of mortality.

Mortality rates were calculated by using the person-years at risk as outlined above. These rates and also all means and proportions were standardized for age by the direct method, with the total population as the standard. Differences in proportions and means in relation to smoking status were tested with the Cochran-Mantel-Haenszel statistic in SAS[22] and by analysis of covariance, respectively. Adjustment for risk factors and calculation of confidence intervals (CIs) for rate ratios were done by using Cox's proportional hazards regression model.[23] These methods are very similar to those that use Poisson regression, but they do not require the assumption of a constant hazard within the individual person-years of follow-up. Dummy variables were used in the models to assess the effects of various risk factor categories (e.g., duration of smoking, maximum amount smoked, and time since quitting) in ex–cigarette smokers compared with never smokers. Tests for linear trend in these three risk factors among ex–cigarette smokers were computed by including a dummy variable for ex–cigarette smoker and a continuous variable for the relevant risk factor. The coefficient for the continuous variable therefore represents the change in mortality per unit change in the risk factor among ex-smokers and was used as a test for trend in the risk factor. Significant departures from linearity were examined by calculating the difference for the chi-square value for heterogeneity and the chi-square value for linear trend.

TABLE 2—Age-Adjusted Mortality Rates per 1000 Person-Years, by Smoking Status

Smoking Status	Mortality Rate per 1000 Person-Years (No. of Deaths)							
				Neoplasms				
	All Causes	CHD	CVD	Total	SRN[a]	NSRN[b]	Lung Cancer	Respiratory Disease
Never smoker (n = 3105)	10.50 (421)	4.34 (175)	6.06 (240)	2.71 (111)	0.96 (49)	1.75 (72)	0.25 (24)	0.68 (24)
Ex-cigarette smoker (n = 4833)	12.10 (969)	4.72 (379)	6.48 (519)	3.74 (300)	1.51 (121)	2.23 (179)	0.73 (58)	0.95 (75)
Primary pipe (n = 492)	13.94 (113)	5.64 (46)	7.85 (64)	3.37 (27)	1.64 (13)	1.73 (14)	1.00 (8)	1.37 (11)
Secondary pipe (n = 1256)	14.12 (282)	5.92 (120)	8.13 (161)	4.20 (85)	2.43 (49)	1.77 (36)	1.18 (24)	1.00 (20)
Primary cigar (n = 105)	5.04 (9)	1.96 (4)	2.36 (5)	2.48 (4)	0.85 (2)	1.63 (2)	0.45 (1)	0.00 (0)
Secondary cigar (n = 658)	12.64 (132)	3.95 (42)	6.06 (64)	4.15 (43)	2.38 (25)	1.77 (18)	1.91 (20)	0.97 (10)
Current cigarette (n = 7921)	20.95 (2570)	7.56 (929)	10.52 (1292)	6.64 (816)	4.28 (524)	2.37 (292)	2.98 (365)	2.20 (266)

Note. CHD = coronary heart disease; CVD = cardiovascular disease; SRN = smoking-related neoplasm; NSRN = non-smoking-related neoplasm.
[a]Smoking-related neoplasms are malignant neoplasms of the lip (ICD code 140), tongue (ICD code 141), mouth and pharynx (ICD codes 143–149), oesophagus (ICD code 150), and pancreas (ICD code 157); respiratory system neoplasms (ICD codes 160–163) and urinary system neoplasms (ICD codes 188–189); and malignant neoplasms of unspecified site or secondary neoplasms (ICD codes 195–199).
[b]Non-smoking-related neoplasms were all other cancers not classified as smoking related.

For tabulations of smoking status with other baseline characteristics, the number of years since quitting at entry to the study was used instead.

Results

The different smoking categories are shown in Table 1. Of the 7921 (43.1%) men classified as cigarette smokers, 1363 (17.2%) also smoked a pipe and/or cigars. A total of 714 (9.0%) men were recruited into an intervention study and given antismoking advice. The age-adjusted mortality rates for these smoking-status groups are shown in Table 2 by cause or category of death. Current smokers had the highest mortality rates for each group of conditions. Mortality rates for ex–cigarette smokers were between those of never smokers and current smokers, although they usually were closer to the rates for never smokers. Both primary and secondary pipe smokers had significantly elevated mortality rate ratios, around 40% above those of never smokers, for all causes and coronary heart disease. Secondary pipe or cigar smokers had higher mortality compared with primary pipe or cigar smokers, but only all-cause mortality for secondary compared with primary cigar smokers was statistically significant (rate ratio = 2.30; 95% CI = 1.17, 4.52). Secondary pipe smokers did have higher mortality than ex–cigarette smokers for all-cause mortality (rate ratio = 1.17; 95% CI = 1.03, 1.34), coronary heart disease (rate ratio = 1.27; 95% CI = 1.03, 1.56), cardiovascular disease (rate ratio = 1.25; 95% CI = 1.05, 1.49), and smoking-

Note. RR = rate ratio (adjusted for age and employment grade); CI = confidence interval. The rate ratio for never smokers is 1.0.
[a]Rate ratios not calculated because of small numbers. The expected mortality risk for death from all causes, compared with the risk of never smokers, is less than 1.22.

related neoplasm (rate ratio = 1.63; 95% CI = 1.19, 1.49). This difference could not be explained by their previous smoking habits, as cigarette smokers who switched to a pipe consumed significantly fewer cigarettes, smoked for a shorter period, and had given up smoking for longer than cigarette smokers who gave up all forms of tobacco. Multivariate analysis, controlling for these three factors, increased the relative risks for secondary pipe smokers compared with ex–cigarette smokers. No significant differences were found between secondary cigar smokers and ex-cigarette smokers.

We examined the relationship between smoking status and other potentially confounding variables. Current smokers were more likely to be of lower employment grade, had lower systolic blood pressure, and weighed less than never smokers ($P < .001$). No obvious trend was seen for risk factors between never, ex-, and current cigarette smokers except for grade. The proportion of higher grades (administrative and professional/executive) progressively increased with years since giving up smoking (test for linear trend, $P < .001$). Current pipe smokers had similar profiles regardless of whether they had smoked cigarettes in the past. Cigar smokers who had never smoked cigarettes had a more favorable risk factor profile except for being shorter in stature (data available on request).

Because smokers may decide to give up their habit because of preexisting disease, we examined the association between smoking habit and four proxy variables suggestive of preexisting cardiovascular, respiratory, and general disease (Table 3). Former smokers were more likely than current smokers to have a doctor diagnosis of heart disease and hypertension, although the prevalence of

electrocardiogram ischemia was similar for both current and former smokers and greater than that for never smokers. The proportions of reported dyspnea and disease at entry were between those of never smokers and current smokers. In general, smokers who had given up smoking within the last 5 years had higher levels of disease or symptoms than longer-term former smokers.

In view of the inconsistent risk factor profile seen with ex-cigarette smokers, we controlled only for age and grade as potential confounders in all subsequent analyses.

Table 4 shows the age- and grade-adjusted rate ratios for ex-cigarette smokers compared with never smokers by (1) the number of years smoked before giving up, (2) the maximum number of cigarettes consumed for a period of at least 1 year, and (3) the number of years since quitting. Among ex-cigarette smokers, a significant increase in mortality compared with that of never smokers was seen only after 20 years of smoking for all-cause mortality; however, the test for trend for duration smoked was significant for all categories of death except non-smoking-related deaths. Significant increases in mortality were seen as the amount consumed increased, except for non-smoking-related neoplasms. Mortality risk fell significantly with years since quitting for all categories except coronary heart disease and non-smoking-related neoplasms. These two categories showed a marked fall after 10 years, but after that period the risks appeared relatively unchanged.

In this cohort, most of the men started to smoke at a similar age. Therefore, among ex-cigarette smokers, for any given age, duration of smoking will determine the number of years since quitting. Hence, these two variables will be highly (negatively) correlated. They will also be correlated with age. In addition, the maximum amount smoked in any year is likely to be higher in those men who smoked the longest. We did not attempt to control for these highly correlated variables simultaneously in a multivariate model because that would require us to make the strong assumption that the effect of each of these factors on the risk of mortality was multiplicative. Instead, to examine the possible effects of the above factors, we carried out a stratified analysis and fitted models by using a dummy variable for each stratum. That allowed the joint effects of the three factors of interest to be assessed relative to men who had never smoked while controlling for the confounding effects of age and grade (Table 5).

Ex-smokers who never smoked more than 20 cigarettes a day and smoked for less than 20 years showed no evidence of any increased mortality risk for either all-cause mortality or other categories. All-cause mortality remained elevated for heavy smokers who smoked for more than 20 years even after 30 years since quitting. Different patterns emerged for coronary heart disease and neoplasms. Coronary heart disease mortality for former persistent heavy smokers showed an initial fall but then remained at a fairly constant level, although after 30 years this risk was no longer statistically significant. For all neoplasm mortality and smoking-related neoplasm mortality, persistent heavy smokers showed a fall in risk with years since quitting.

Discussion

All-Cause Mortality

Former cigarette smokers had mortality risks between those of current cigarette smokers and those of never smokers, a finding similar to those of other cohort studies.[2,3,7,9] Mortality increased with duration of smoking and maximum amount consumed and decreased with years since quitting. After stratification for these three factors, both the maximum amount smoked and the duration of smoking were independently important in determining mortality risk. Although the risk for ex-smokers fell substantially compared with that for current smokers, persistent heavy smokers showed little further decline with increasing years since quitting. Light smokers who had smoked for less than 20 years had no evidence of any increased risk.

Coronary Heart Disease Mortality

Ex-cigarette smokers showed increased mortality from coronary heart disease compared with never smokers. This mortality risk increased with amount consumed and duration of smoking. A sharp fall in mortality was seen in the first 19 years after quitting. However, after this period there appeared to be little further reduction in risk, and there was no significant trend with years since quitting. Persistent heavy smokers showed a significant elevated risk up to 30 years after quitting.

Several studies have suggested that a risk for coronary heart disease mortality may persist for ex-smokers; however, this risk was small and not always statistically significant.[4,5,7,8,10] Prospective studies that have examined the effects of years since quitting have noted either a sudden fall in risk with little further decline[7,24] or a slower continual decline.[2–4,10] In general, cohort studies support our finding,[2,3,10] whereas case–control studies suggest that the risk for coronary heart disease mortality or nonfatal infarcts falls quickly with no persistent difference between ex–cigarette smokers and never smokers.[11,12] Both the latter studies have had insufficient power to detect a small excess risk.

Fibrinogen has been shown to be elevated in smokers[25] and is a strong predictor of coronary heart disease.[26,27] The levels for ex–cigarette smokers revert to those of never smokers after several years of cessation.[11,25,28] It is an acute and reversible mechanism by which coronary heart disease risk may change. But persistent heavy smokers may have developed irreversible changes in the coronary architecture, unrelated to fibrinogen. A study of postinfarction angina noted an acute reduction in angina for ex-smokers compared with those who continued to smoke, but no difference by 6 years.[29] The role of a reversible, as well as an irreversible, component may also explain the relatively modest reductions for coronary heart disease mortality seen in intervention trials.[9,30,31]

Neoplasm Mortality

Ex–cigarette smokers showed an elevated risk for neoplasm mortality, lung cancer in particular. Significant trends were seen only for smoking-related neoplasms and lung cancer with amount smoked and duration of smoking. Persistent heavy smokers showed a gradual decline in mortality risk with years since quitting, with the risk after 30 years still raised but no longer statistically significant. A persistent elevated risk for both lung cancer and smoking-related cancers has been seen with both mortality data[4,5,7] and incidence data.[32] Intervention studies, including a subsample of subjects recruited from this cohort, also failed to show a reduction of risk from lung cancer.[9,30] A smoker inhales substances that may act as initiators and promoters of carcinogenesis.[33] Smoking cessation may prevent new lesions from developing but may only retard preexisting early lesions, which continue to develop at a slower rate.

Pipe and Cigar Smokers

Many cohort studies have reported the combined mortality rates of cigar and pipe smokers or have failed to distinguish primary from secondary pipe or cigar smoking.[2,3,5,6,8,10,24,34,35] This distinction is important because smokers from older cohorts are more likely to be primary pipe or cigar smokers, whereas recent cohorts will have more secondary pipe or cigar smokers. A recent study reported that 90% of the cigar smokers were ex-cigarette smokers.[36] The small group of primary cigar smokers showed no evidence of an increased mortality risk compared with never smokers. Both primary and secondary pipe smokers were at greater risk of death from coronary heart disease than cigar smokers. This result contradicts some studies[2-4,37] but is supported by another.[8] Both cigar smoking and pipe smoking have been associated with either a greater risk of coronary heart disease mortality[36-38] or no excess risk.[6,24] These inconsistencies may reflect true differences between populations in the type and amount of tobacco consumed, but more likely they reflect confounding by socioeconomic status or other factors, which will differ for different time periods and countries.

Secondary pipe and cigar smokers had a slightly greater risk of death from coronary heart disease than primary pipe or cigar smokers, as has been noted elsewhere,[10] although this difference was not statistically significant. Higher carboxyhemoglobin, higher serum cotinine levels, and an increase in fibrinogen levels have been found in secondary compared with primary cigar smokers.[25,39] Secondary pipe or cigar smokers also had greater risks of smoking-related neoplasm death compared with pure pipe or cigar smokers. Although that could have occurred by chance, it is interesting that the rates of non-smoking-related cancers for primary and secondary pipe and cigar smokers were almost identical. This increased risk may reflect a residual carcinogenic effect from cigarettes. In addition, when cigarette smokers change their habit to pipe or cigars they consume more tobacco and inhale to a greater degree.[40] Changing to a pipe was associated with significantly greater mortality than total cessation of smoking, but no real difference was seen for subjects who took up cigar smoking.

With any observational study, it is unclear whether the benefits seen for smoking cessation are due to smoking cessation itself or to other alterations in life circumstances that may occur concurrently. Baseline differences in other risk factors for this cohort showed little consistent pattern apart from socioeconomic status, as in other studies.[41-46] Ex-smokers may pursue a more healthy life-style, but this is probably a more recent phenomenon.[45]

Smoking status was measured only at baseline and may have been misclassified owing to recidivism among ex-smokers. Empirical data from other studies[9,47] suggest that recidivism usually occurs within the first few years of stopping. Heavy smokers are usually,[9,48] but not always,[47] reported as more likely to resume smoking. Recidivism will in general result in an underestimate of the benefits of giving up; however, in the group of heavy smokers who had given up for more than 30 years, this is unlikely to be a serious bias.

Some smokers are likely to give up because of newly diagnosed disease. This is supported by the observation that ex-smokers who had given up smoking for less than 5 years were more likely than current smokers to have a diagnosis of heart disease or hypertension and to complain of dyspnea. These differences were small and are unlikely to explain any persistent risk among ex-smokers who have given up for more than 30 years, although they may result in underestimating the short-term benefits of giving up.

Conclusions

Ex-smokers show a reduced mortality risk compared with current smokers. This risk may remain persistently higher than the risk for never smokers, depending on previous smoking history and the number of years since quitting. Duration of smoking[10] or consumption of cigarettes[11] alone does not explain the different mortality patterns. Smokers who change to a pipe or cigars appear to retain a greater risk than pipe or cigar smokers who have never consumed cigarettes. Changing to a pipe was associated with a higher mortality risk than that for ex-cigarette smokers who no longer smoked any form of tobacco, but no difference was found for subjects who switched to cigars.

These results have implications for any future predictions about mortality trends for smoking-related diseases. The mortality risk of nonsmokers will differ depending on the proportion of ex-cigarette smokers and their past smoking histories. Hence, the true risk for this group will differ both for different countries and over different time periods. Current life expectancy estimates for ex-smokers[49] may not be valid for future generations.

It is important that the public be aware that whereas stopping smoking results in a markedly diminished risk, a residual excess risk may persist even after many years. The suggestion that ex-smokers have no greater risk than never smokers[50,51] may be counterproductive. Smokers may believe that continuing to smoke is not deleterious as long as they eventually give up. The amount, duration, and period since giving up appear to be important in determining mortality risk.

The Risk of HIV Infection in a National Sample of Women with Injection Drug–Using Partners

Stephanie Torta, PhD, Mark Beardsley, RhD, Sherry Deren, PhD, and W. Rees Davis, PhD

ABSTRACT

Objectives. This study reports on a large, national cohort of women with injection drug–using sex partners. Information is provided on demographic characteristics; human immunodeficiency virus (HIV) risk factors, including unprotected sex and incidence of sexually transmitted diseases; use of noninjected drugs; HIV serostatus; and other selected health variables.

Methods. A sample of 5162 heterosexual women was recruited for a national acquired immunodeficiency syndrome (AIDS) research and demonstration project. A structured interview was administered, and the women had the option of undergoing HIV testing. Statistical analyses compared three groups on variables of interest: women with single sex partners, women with multiple partners, and women with multiple partners who exchanged sex for drugs and/or money.

Results. These groups differed significantly on virtually all of the demographic and risk variables examined. Women with multiple partners who exchanged sex for drugs and/or money were at higher risk for HIV than women in the other groups, even when selected demographic variables were controlled.

Conclusions. Research is needed on the efficacy of prevention efforts involving these diverse groups of women at risk for AIDS. (*Am J Public Health.* 1994;84:1243–1249)

Introduction

Stimulated by World AIDS Day in December 1990, which highlighted the lack of knowledge regarding HIV in women, efforts have begun to focus on gaining the information necessary to treat and prevent this disease among women.[1] Women with injection drug–using sex partners are among those at highest risk and are the most rapidly growing group of adults with AIDS in the United States.[2,3] As of June 1993, 7495 US women had acquired AIDS as a result of their sexual relationship with an injection drug user.[4] Also, of the 3054 women who contracted AIDS as a result of having sex with an HIV-infected person with risk unspecified, many may have been partners of injection drug users and unaware of their partner's drug use.[5]

Although women with injection drug–using partners often have no history of using injected drugs themselves, many use noninjected drugs, especially crack.[6–8] Interrelationships have been demonstrated among crack use, sexually transmitted diseases, and HIV infection. Crack use is a risk factor for HIV because of its association with high-risk sexual behaviors.[9–11] Cocaine use is also associated with syphilis,[12–14] and sexually transmitted diseases in general are implicated in the enhancement of HIV transmission.[15]

Unfortunately, the number of women who acquire AIDS as a result of sex with infected men is likely to continue to increase.[3] Even when other factors are controlled, male-to-female transmission is more efficient than female-to-male transmission.[16] Also, there are currently more infected men than women, thus increasing the probability that a woman would have an infected partner, especially in neighborhoods with high concentrations of infected men.

Although there is a pressing need to develop programs aimed at reducing HIV risk behaviors among women with injection drug–using partners, little is known about this group.[1,17] Even in the midst of the AIDS epidemic, drug treatment programs have made few efforts to work with partners of injection drug users.[18] If meaningful intervention programs are to be developed for women with injection drug using sex partners, more information is needed about their extent of risk and other aspects of their lives.

In this study, data from a large national cohort of women with injection drug–using sex partners were analyzed. As specified by the research protocol, the women reported one or more injection drug–using sex partners and no such drug use themselves in the 6 months prior to their initial interview.

Previous analyses of an earlier version of this data set (n = 3589) focused on racial/ethnic differences among the women in sexual risk, drug use, and incidence of sexually transmitted diseases.[8] Major racial/ethnic groups were African Americans, Whites, Puerto Rican Latinas, and other Latinas (primarily Mexicans). Results indicated that, for women with one injection drug–using partner, White women reported a higher frequency of unprotected vaginal sex than did those in the other groups. Among

This paper was accepted November 24, 1993.

women with multiple partners, there were no racial/ethnic differences in mean frequency of unprotected vaginal sex. African Americans were more likely to report using crack, alcohol, and cocaine than were those in the other groups. African Americans and Whites generally reported more sexually transmitted diseases than did women in either Latina group.

Because patterns of sexual activity vary and may have a major impact on the degree of AIDS risk as well as other health and economic factors, it was decided to compare three behaviorally defined groups of heterosexual women with injection drug-using partners. These groups were composed of women who, during the 6 months prior to the interview, (1) had single partners, (2) had multiple partners and did not exchange sex for drugs and/or money, and (3) had multiple partners and did exchange sex for drugs and/or money. The three groups were compared on demographic and economic characteristics, involvement with the criminal justice system, sexual risk behaviors, non-injected drug use, and health characteristics. The effect of the grouping on HIV risk and other variables was then examined while controlling for selected demographic characteristics.

Methods

Procedure

The National AIDS Demonstration and Research program, on which this research was based, was implemented in 1987 by the National Institute on Drug Abuse and targeted two "hard to reach" groups: out-of-treatment injection drug users and those with injection drug-using sex partners. The goals were to collect information concerning HIV risk and to test the efficacy of various AIDS prevention strategies. Sixty-three sites were involved across the continental United States, in Hawaii and Puerto Rico, and along the US-Mexican border. Both target groups were offered equivalent incentives for participation. This paper reports only on heterosexual women with injection drug-using sex partners.

Individual sites determined their own recruitment strategies but were generally guided by indigenous outreach workers with knowledge of local drug using networks. To maximize the participation of this "hidden population," recruitment efforts were directed toward "street" locations where drug users congregate, as well as places where their partners are likely to be found (e.g., family-planning/obstetrical-gynecological clinics, housing projects, shelters, social service agencies, prisons). Efforts were made to recruit sex workers because many have injection drug-using partners.[7] Prior to any intervention, the women participated in a structured 45-minute interview. Topics included demographic and economic characteristics, involvement with the criminal justice system, sexual risk behaviors, non-injection drug use, incidence of sexually transmitted diseases, and other health characteristics. Data were collected from January 1988 through June 1991. Test-retest reliability (over an interval of 2 to 14 days; n = 196) was high for questions on number, gender, and injection drug-using status of sex partners and on exchange of sex for money or drugs (kappa range of .53 to 1.00). Test-retest correlations for the most risky sexual behaviors were .66 (vaginal sex) and .79 (anal sex). Test-retest correlations for frequency of noninjection drug use, based on ever having used a particular drug, ranged from .15 for heroin to .75 for alcohol. Women were offered HIV testing, and, when they were tested by National AIDS Demonstration and Research projects, HIV serostatus was included in the data set. In order to minimize responding based on "self-diagnosis," questions regarding history of sexually transmitted diseases were worded as follows: "Have you ever been told by a doctor or a nurse that you had . . .?" Systematic quality control procedures were implemented by a research firm under contract to the National Institute on Drug Abuse to verify client eligibility criteria and to assess the consistency of responses within each questionnaire.

Sample

The sample consisted of 5162 heterosexual women with injection drug-using partners; 53.1% were African Americans, 15% were Puerto Rican Latinas, 15% were Mexican Latinas, 12.5% were Whites, and 4.4% were Asian Americans, Native Americans, or other Latinas. The geographic distribution was as follows: 30% from the South, 27% from the Northeast, 23% from the West, 11% from Puerto Rico, and 10% from the North Central region.

Only 43% were high school graduates, and 15.5% were employed (full or part time). Homeless women (living on the streets or in a shelter) accounted for 11.6% of the sample. Regarding sexual activity, 53% (n = 2734) reported a single injection drug-using partner, 23.3% (n = 1205) reported multiple partners but had not exchanged sex for drugs and/or money, and 23.7% (n = 1223) reported multiple partners and had exchanged sex for drugs and/or money.

Statistical Analyses

One-way analyses of variance (ANOVAs) and chi-square tests were used to compare the three groups on demographics, drug use, sexual behavior, and health characteristics. Pairwise comparisons of means were conducted with Tukey's studentized range test when a significant ($P < .05$) ANOVA F value was obtained. All chi-square tests producing a significant overall finding ($P < .05$) were followed up with a series of 2×2 chi-squares to compare all three possible pairs of groups. Chi-square follow-up tests were reported as significant at the $P < .05$ level or better.

A second stage of analysis was conducted to assess whether grouping predicted risk behaviors and health outcomes when major demographic variables were controlled. Both multiple regression (sex risk and drug use behaviors) and logistic regression (dichotomous health and AIDS outcomes) were used. The grouping effect was examined in two ways: (1) by comparing women who had multiple injection drug-using partners but who did not exchange sex for drugs and/or money and those who had single partners and (2) by comparing women who had multiple injection drug-using partners and who did exchange sex for drugs and/or money and those who had multiple partners but did not exchange sex for drugs and/or money. Four series of regression analyses were conducted, since sex risk and drug use behaviors (continuous variables) and health and AIDS outcomes (dichotomous variables) were analyzed separately for each of the two group comparisons. The following variables were included in all regression analyses: age, African-American ethnicity, Latina ethnicity, northeastern region, southern region, western region, homelessness, and high school education. These independent variables (except for age) were coded dichotomously.

Results

Significance levels for the variables discussed in this section are reported only in the tables.

Demographic Characteristics

Table 1 indicates many significant differences among the groups. Women

with multiple partners who exchanged sex for drugs and/or money were most likely from the Northeast (35.8%); women with single partners were most likely from the South (32.8%) (χ^2 = 222.47). While women in all three groups were most likely to be African-American (χ^2 = 311.60), there were significant differences by group: two thirds of women with multiple partners were African-American, compared with about one half of the other groups. About 40% of women with single partners were Latina, in comparison with less than 20% of women who exchanged sex for drugs and/or money. Women with single partners (mean age = 30.3 years) were slightly older than those in either of the other two groups (F = 22.94, df = 25159) (see Table 1 for more detail).

Women with multiple partners who exchanged were more likely to be homeless (17.9%) than either women with single partners (7.5%) or those with multiple partners (11%) (χ^2 = 95.20). They were less likely to be high school graduates (40.0%) than either women with single partners (41.7%) or women with multiple partners (48.8%) (χ^2 = 22.98) and less likely to have children living with them (35.6%) than either women with single partners (66.5%) or women with multiple partners (60.1%) (χ^2 = 334.77). Women with multiple partners who exchanged were also more likely to have been in drug treatment (41.7%) than either women with single partners (15.3%) or those with multiple partners (24.7%) (χ^2 = 324.61).

Economic Characteristics and Criminal Justice Involvement

Table 2 displays information regarding economic characteristics and experiences with the criminal justice system. Both women with single partners (16.9%) and those with multiple partners (16.7%) were more likely to be employed than were women with multiple partners who exchanged sex for drugs and/or money (11.6%) (χ^2 = 19.87). Women with multiple partners who exchanged (57.8%) were more likely to report income from illegal sources than were either women with single partners (5.8%) or those with multiple partners (8.6%) (χ^2 = 1582.69). Although most women with multiple partners who exchanged (55.4%) reported income from welfare, the proportion was still significantly less than the proportions of women with single partners (67.5%) and women with multiple partners (66.1%) (χ^2 = 51.68). More women with multiple partners who exchanged reported income from sex partners (44%) than either women with single partners (28.2%) or those with multiple partners (25.3%) (χ^2 = 124.10).

Women with multiple partners who exchanged sex for drugs and/or money were also most likely to have had experience with the criminal justice system. More than 58% of these women had been

imprisoned, in comparison with 32% of women with single partners and 38.1% of women with multiple partners (χ^2 = 254.80). Women with multiple partners who exchanged (10.6%) were also more likely to be facing criminal charges at the time of the interview than were women with multiple partners (3.8%) or women with single partners (3.5%) (χ^2 = 90.38).

Sexual Risk Behaviors

Three sexual behaviors were examined (see Table 3): frequency of unprotected vaginal sex, oral sex (fellatio), and anal sex. Also included was the sum of the three unprotected sexual activities and the mean percentage of condom use for the three activities. Although women with multiple partners who exchanged sex for drugs and/or money (34%) reported a higher mean monthly percentage of condom use across all three activities than did women with single partners (7.8%) or those with multiple partners (15.5%) (F = 486.80, df = 2512), the frequency of unprotected sex in this group was also significantly higher than in the other groups. Mean monthly frequency of unprotected vaginal sex among women with multiple partners who exchanged was 34.5, significantly more than women with single partners and women with multiple partners (22.7 and 24.2, respectively; F = 548.11, df = 2515). Unprotected anal sex was a relatively low frequency behavior. Women with multiple partners who exchanged (56.5) reported a higher total number of unprotected sex acts than did women with single partners (28.6) and women with multiple partners (33.1) (F = 123.81, df = 2515). Finally, women with multiple partners who exchanged had significantly more injection drug–using partners (mean = 9.5) than did women with multiple partners (mean = 1.4).

Noninjection Drug Use

During the 6 months prior to the interview, the mean monthly frequencies of crack, alcohol, cocaine, marijuana, and noninjection heroin use, analyzed individually for each substance, were highest for women with multiple partners who exchanged sex for drugs and/or money. The most frequently used drugs were crack, alcohol, and noninjected cocaine. As Table 4 indicates, the frequency of crack use for women with multiple partners who exchanged was extremely high (50.1); among women with single partners and women with multiple partners, the frequencies were considerably lower (7.3 and 10, respectively). The mean monthly frequency of alcohol use among women with multiple partners who exchanged was 31.6; the corresponding figures for women with single partners and those with multiple partners were 12.9 and 18.2 (F = 110.97, df = 2515). Women with multiple partners who exchanged (22.4) also reported more frequent noninjected cocaine use than did either women with single partners (4.5) or those with multiple partners (6.1) (F = 170.5, df = 2,515).

Health Characteristics

The health characteristics assessed (see Table 5) were prevalence of gonorrhea, syphilis, chlamydia, genital herpes, genital sores, and persistent yeast infections; perceived likelihood of contracting AIDS; perceived health status; pregnancy status; and HIV serostatus. The most prevalent sexually transmitted disease was gonorrhea; 40.1% of women with multiple partners who exchanged reported ever having gonorrhea, in comparison with 25.8% of women with multiple partners and 13.4% of women with single partners (χ^2 = 369.32). Women with multiple partners who exchanged were also more likely to report ever having syphilis (17.7%) than women with multiple partners (7.9%) or women with single partners (4.1%) (χ^2 = 206.69). Finally, women with mul-

tiple partners who exchanged (22.5%) were more likely than women with multiple partners (13%) and those with single partners (8.1%) to report ever having genital sores ($\chi^2 = 159.45$).

More women with multiple partners who exchanged reported being pregnant (16.43%) than either women with single partners (11.98%) or those with multiple partners (9.93%) ($\chi^2 = 23.71$). Approximately 30% of the sample underwent HIV testing. Women with single partners and women with multiple partners (both 33.7%) were more likely to report having had an HIV test than women with multiple sex partners who exchanged (20.8%) ($\chi^2 = 73.58$). Although more women with multiple partners who exchanged (7.9%) were confirmed as seropositives than women with single partners (5.4%) and women with multiple partners (4.4%), the differences were not statistically significant ($\chi^2 = 3.60$). Finally, among women who were not tested, those with multiple partners who exchanged (21.4%) were more likely to report that they had a high or sure chance of contracting AIDS than were either women with single partners (13%) or women with multiple partners (11%) ($\chi^2 = 41.73$).

Effects of Group Status

As Table 6 indicates, most of the differences in sex risk and drug use behaviors between women with multiple sex partners who exchanged sex for drugs and/or money and women with multiple partners who did not do so remained highly significant, even when the effects of demographic variables were taken into account. Thus, the effect of exchanging was significant above and beyond the combined influence of age, ethnicity, geographic region, level of education, and homelessness. However, the effect of having multiple sex partners (vs having one partner) was less pronounced. This effect remained significant for alcohol and marijuana use, but there were no differences between women with multiple partners and women with single partners in the use of crack, cocaine, or heroin or in unprotected sex when demographic characteristics were controlled.

The results presented in Table 7 suggest that the effects of (1) having multiple sex partners vs a single sex partner and (2) having multiple partners and exchanging sex for drugs and/or money (among women with multiple partners) are both associated with a significantly greater likelihood of having a sexually transmitted disease and having had each of several specific illnesses. Thus, women with multiple sex partners were about twice as likely (odds ratio [OR] = 2.16) as women with single sex partners to have had at least one sexually transmitted disease, and, among women with multiple partners, those who exchanged (OR = 1.80) were more likely than those who did not to have had a sexually transmitted disease, even when demographic factors were taken into account. The effects of having multiple partners vs having a single partner and of exchanging vs not exchanging were also associated with a significantly greater likelihood of having had genital herpes, gonorrhea, syphilis, and genital sores.

Discussion

Several points must be made before considering the implications of these data. First, National AIDS Demonstration and Research projects were not planned as population studies, and subjects were not randomly selected. Thus, the data were not intended to represent the universe of women with injection drug–using sex partners. Also, the data, excluding HIV serostatus, were based on self-report. There may be limitations to the precision of these data, especially since most questions concerned behavior over a period of 6 months. Finally, in order to have been involved in these projects, women had to have some knowledge of a partner's injection drug use. As noted previously, many women probably are unaware of their partner's injection drug use and thus constitute one particularly vulnerable group not represented here. Nonetheless, conclusions drawn from this research can be helpful in planning prevention strategies as well as indicating areas for future research.

Overall, considerable numbers of these women were poorly educated and unemployed. Also, many had jail or prison experiences, were homeless, and had significant drug problems. These facts suggest that their daily need to survive may take precedence over other motivations, including the prevention of AIDS. AIDS is but one of many concerns faced by these women, most of whom reside in economically and socially devastated inner cities. Experience with the National AIDS Demonstration and Research projects indicates that women with injection drug–using partners can be reached and appear interested in reducing their HIV risk.[19] However, it must be recognized that the more immediate goal of HIV prevention may not be realized without addressing the broader social issues affecting these women's lives.

The major conclusion reached from these data is that differences among women with injection drug–using partners are clearly associated with the type of sexual contacts they have with men. On nearly all of the characteristics examined, even when major demographic variables were controlled, findings indicated that women who traded sex for drugs and/or money lead lives that are the most chaotic, the least healthy, and the most risky. The differences are not only statistically significant but are of a magnitude that is very dramatic in terms of what they mean in "real life." As poignantly written by researchers involved in a Miami-based project, "women who exchange sex for crack [as do many in this group] experience a level of human suffering previously unknown in the street drug scene."[20] Women who exchanged were much more likely to be homeless, to have been incarcerated, and to have engaged in illegal activities as a way to survive. Although they were more likely to report that their partners used a condom during sexual activities, a better indication of HIV risk was the significantly higher amount of unprotected high risk (vaginal and anal) sex in which they engaged. Also, they had significantly more injection drug–using partners than did women in the other groups, further increasing their risk for exposure to the virus. Crack use was rampant in this group, indicating a pressing need for drug treatment as a part of HIV prevention. Also, the rate of sexually transmitted diseases was extremely high, probably as a result of urban poverty, social disintegration, prostitution, and the exchange of sex for drugs.[21] The rate of seropositivity in this group was higher than that in the other two groups, but not significantly so. However, because serostatus results were available for only 30% of the sample, it is highly likely, given the levels of risk reported among this group, that the difference would have been

significant if a larger number of women had been tested.

Much that has been written about sex workers and AIDS has focused on the role of the former as "vectors of transmission" into the heterosexual community.[1] The dangers of this type of life for the women themselves have often not been addressed. Yet, with the relative efficiency of transmission from an infected man to a woman and the high probability in certain communities that women have sexual contacts with large numbers of infected men, these women probably face a greater risk of being infected themselves than infecting others.

Women with single partners presented a different picture in terms of HIV risk. They were most likely to receive an income from public assistance and to have children living with them. They were least likely to have been in jail or prison or in a drug treatment program. Their men were also least likely to use a condom during sexual activities. Thus, although they had a lower frequency of unprotected vaginal sex than the women with multiple partners who exchanged sex for drugs and/or money, women with a single injection drug–using sex partner must still be considered at high risk. Because their reports of noninjected drug use were relatively low, as was their incidence of sexually transmitted diseases, they are mainly at risk through unprotected sex with a single injection drug user. While condom use is recommended as an HIV prevention strategy for all sex partners of injection drug users, qualitatively different relationships (e.g., monogamous couples vs women who trade and their clients) may call for different approaches to condom use negotiation. This issue needs more investigation. Also recommended is more research on developing and testing protective methods that are controlled by women, including the recently introduced female condom.[22]

Women with multiple sex partners who did not trade sex for drugs and/or money appeared to be more like women with single sex partners on both demographic characteristics and level of HIV risk. Thus, they are at risk primarily through unprotected sex with multiple injection drug users.

Many research questions remain to be investigated. For example, which demographic and drug use variables predict group status? Also, more information is needed regarding the relative efficacy of different models of outreach and intervention with these women. HIV risk reduction efforts among drug users have generally focused on two behavior change strategies: social learning techniques (to teach the skills necessary for risk reduction) and the community organizing model, which is based on changing norms, values, and practices directly connected with HIV risk reduction.[23] It is not yet clear which is most relevant to women with injection drug using sex partners. Finally, the present study focused on a single point in time. One particular variable that needs to be examined more closely is the past use of injection drugs by this population. Unfortunately, detailed information regarding prior injection behavior, including when drug injection stopped, was not available from this sample. Additional research is required to assess the extent to which risk behaviors among identified groups of women with injection drug–using partners vary over time and to identify those factors affecting change. □

A Recent Decline in Cocaine Use among Youthful Arrestees in Manhattan, 1987 through 1993

ABSTRACT

Objectives. Cocaine use among youths as measured by several annual surveys was most popular from about 1979 to 1986, after which it declined. This study carefully examines the nature of the decline by focusing on microdata for youthful arrestees in Manhattan.

Methods. Multiple statistical analyses examine whether the decline in cocaine use detected by urinalysis is attributable to fewer arrested youths born more recently having become regular users (cohort effect), to regular users decreasing their consumption (period effect), or to changes in arrest or sampling priorities (artifact).

Results. All analyses suggest that the dramatic decline in detected cocaine use among arrestees—from 69% in 1987 to 17% in 1993—was a cohort effect. Detected cocaine use, which was highest (78%) among arrestees reaching 18 in 1986 at the height of the crack epidemic in New York City, subsequently declined to a low of 10% among arrestees reaching 18 in 1993.

Discussion. These findings suggests that the epidemic in use of cocaine and crack entered a decline in the late 1980s. However, widespread use of these drugs will probably continue to prevail as an aging population with established habits persists in its use. (*Am J Public Health.* 1994;84:1250–1254)

Introduction

This paper examines recent trends in illicit drug use among very high-risk youths who have problems with both drug use and the law. Persons tend to establish lifetime drug use patterns by their teens or mid-20s.[1–4] Many adults eventually stop using certain drugs or decrease their frequency of use. However, some persons who begin using or abusing illicit drugs as teens persist in such use for a long time. Hence, trends in drug use among youths provide a harbinger of future drug use patterns by these persons as adults. For example, in New York City today, the majority of heroin injectors are currently in their late 30s, 40s, and 50s, and began injecting heroin in the 1960s and early 1970s.[5–10]

Table 1 reports trends in the use of certain illegal drugs among youths from three major ongoing surveys. Monitoring the Future obtains self-reported drug use histories from a national probability sample of high school seniors.[11] The National Household Survey on Drug Abuse uses a nationwide sample of households.[12,13] The Drug Use Forecasting (DUF) program, started in 1987, collects urine specimens along with self-reported information from a sample of arrestees at each of 24 central booking facilities nationwide.[14–16] Results from the first two surveys exhibit comparable trends in drug use over time; those from the Drug Use Forecasting program in Manhattan reveal much higher levels of drug use than the other two surveys.

A recent report by the US General Accounting Office suggests that the overall prevalence of drug use measured by each of these three surveys can be misleading.[17] Self-reported data from Monitoring the Future and the National Household Survey may be biased downward by subjects' unwillingness to report drug use and by the fact that many serious drug abusers neither remain in school nor live in stable households. The Drug Use Forecasting program obtains an objective measurement of recent drug use with urine samples. Through use of the enzyme-multiplied immunoassay technique urinalysis screen, it detects cocaine use within the past 48 to 72 hours but does not distinguish mode of use (i.e., snorting, smoking, or injecting).[15] Consequently, many youthful arrestees detected as recent cocaine users may have been crack users.

The Drug Use Forecasting sample of arrestees, however, is not representative of the general community, and so the prevalence of detected drug use within it is typically much higher.[17] Most of its youthful arrestees in Manhattan were charged with a serious crime, 80% for a felony; additionally, most are male (82%) and minority (80% Black or Hispanic).

This study focuses less on the overall magnitude of drug use and more on changes over time, especially the decline in the detected use of cocaine from 69% in 1987 to 17% in early 1993 among Drug

[a]The Drug Use Forecasting–Manhattan program, which detects recent use via urinalysis, recruits around 200 arrestees under age 21 per year resulting in standard errors for drug use prevalence on the order of 3.0%.
[b]First quarter results only.
[c]Since 1988, the Drug Use Forecasting program has tested for cocaine, opiates, cannabis, amphetamines, barbiturates, benzodiazepines, methadone, methaqualone, propoxyphene, and phencyclidine.
[d]From Johnston et al.[11] Monitoring the Future interviews about 16 000 high school seniors each year regarding drug use within the past 30 days and thus obtains extremely accurate prevalence rates with standard errors on the order of 0.2%.
[e]From the National Household Survey on Drug Abuse.[12,13] The National Household Survey on Drug Abuse, which also is concerned with drug use within the past 30 days, typically surveys more than 1000 persons aged 18 to 25 in each sampling year, which results in standard errors on the order of 0.7%.
[f]Question initiated in the 1979 survey.

Use Forecasting Manhattan arrestees under age 21. The overall trends in the use of any illicit drugs, as shown in Table 1, primarily reflect changes in the popularity of marijuana—the most commonly used illicit drug—which peaked in 1979 and declined thereafter. A previous study reported in this Journal documented that these national trends are mirrored by those among high school students in New York State.[18]

Table 1 indicates that cocaine use among youths nationally also peaked by 1979. Unlike marijuana, however, cocaine maintained its popularity through about 1986, after which time its use declined precipitously. This is documented in other studies,[23] in which cocaine use increased from about 1979 and then declined starting in the late 1980s. Overall drug use and the use of heroin declined in the late 1980s, suggesting that these former cocaine users did not replace cocaine with other known hard drugs. The congruence of findings from these three extensive data sets, along with observations by ethnographers,[19–22] thus provides strong evidence of a *passing cocaine fad among youths* as well as among adults.

Methods

The observed decline in detected cocaine use among Drug Use Forecasting–Manhattan youthful arrestees from 1987 to the first quarter of 1993 (1Q93) may have resulted from either of three phenomena: (1) a decline in use, as youths who previously used cocaine cut back on their frequency of use or terminated use completely; (2) a decline in initiation, as fewer of those youths who were born more recently initiated regular cocaine use; or (3) a change in sample characteristics, as changes in either policing priorities or Drug Use Forecasting–Manhattan recruitment procedures resulted in there being fewer cocaine-using offenders recruited in more recent samples.

Three statistical techniques were used to analyze this decline: an age-period-cohort analysis, logistic regression, and postdiction. The age-period-cohort analysis examined a two-way table displaying trends in prevalence of detected cocaine use as a function both of birth year down the rows (cohort effect) and of interview year across the columns (period effect). Any detectable period effect reflected both changes in drug use over time and changes in Drug Use Forecasting sampling procedures. An age effect would be observed as any differences across diagonals.

Logistic regression differs from ordinary least-squares regression primarily in that the dependent variable represents the odds for a particular trait—in this case, detected cocaine use. (For a thorough discussion of the properties of logistic regression, see Hosmer and Lemeshow.[24]) Just like ordinary least-squares regression, logistic regression has the important property of estimating the variation associated with each independent variable simultaneously and, thereby, controlling for the influence of all other variables included in the analysis. To control for any changes in the sample composition over time, the following arrest and demographic variables were included in this analysis: (1) most serious arrest charge, (2) whether the arrest was for a misdemeanor or a felony, (3) sex, and (4) race/ethnicity. Birth year was included to measure changes across birth cohorts. Similarly, interview year was included to identify any residual decline

resulting from former users decreasing or terminating use, controlling for both changes in sample composition and variation across birth cohorts. Quarter was included to detect any seasonal variation.

Postdiction examined the extent to which differences across birth cohorts and sample composition alone and in combination could account for the observed decline. The first step was to estimate a logistic regression model with detected cocaine use as the dependent variable. The independent variables included the sample composition variables and/or birth year. This regression model explicitly *excluded* the Drug Use Forecasting interview year and quarter as independent variables in order to determine how variation over time in the sample composition and birth cohort variables could reproduce (or postdict) the observed decline in detected cocaine use. The second step was to determine each subject's probability of detected cocaine use by employing the coefficient estimates from the logistic regression model. The last step was to calculate the postdicted rate of detected cocaine use for each year as the sum of the appropriate individual, postdicted probabilities.

Results

The substantial variation in detected cocaine use across birth years and the lack of a decline across interview years by birth cohort reported in Table 2 suggest that the decline in detected cocaine use was predominately a cohort effect and that few cocaine-using criminal offenders reduced or terminated use of cocaine. Overall, detected cocaine use declined dramatically across birth cohorts from a high of 78% among arrestees born in 1968 to a low of 10% among those born in 1975 and 1976.

The logistic regression analysis further documents the contribution of each explanation for the observed decline. The estimated odds of detected cocaine use reported at the bottom of Table 3 are for the reference population, persons whose attributes matched the reference levels for each attribute analyzed (identified in italics). These odds are referred to as the "reference rate." Hence, urine tests of youthful, male, Black arrestees for a larceny misdemeanor, interviewed by Drug Use Forecasting–Manhattan in 1Q87 and born in 1967, were nine times as likely to give evidence of cocaine use as not. (These odds of 9:1 correspond to a 90% probability of detected cocaine use.)

Table 3 also reports estimated odds ratios associated with each attribute level that differs from the reference level. The odds of detected cocaine use for nonmembers of the reference population equals the product of the reference rate times the odds ratio associated with each attribute differing from the reference level. For example, the analysis indicates that arrestees for drug possession whose other attribute values matched the reference levels were about twice as likely as the reference population to be detected as cocaine users. Their estimated odds are 18:1 (2.04×9).

The Wald statistics reported in Table 3 test whether the variation in estimated odds ratios across the levels of each

Postdicted by birth cohort differences alone	67	59	49	36	25	21	18

attribute are statistically significant, based on an asymptotic χ^2 distribution. The Wald statistics also provide a rough rank ordering of the partial influence of each independent variable, controlling for all others. The most important variable was birth year, followed by arrest charge, misdemeanor/felony, and quarter. The variation in detected cocaine use associated with interview year was not statistically significant ($\alpha = .01$ level), suggesting that the observed decline probably did not result from a reduction or termination of cocaine use.

Youthful arrestees born in 1968 exhibited the highest rate of detected cocaine use, controlling for the influence of all other variables. These youths reached age 18 in 1986, which was near the height of the epidemic-like growth in the prevalence of crack use.[25–27] The rate of detected cocaine use declined steadily among arrestees born after 1968. Those born in 1976 were 14 times less likely to be detected as cocaine users than those born in 1968 (1.73/0.12), controlling for all other variables.

This finding helps explain the observed decline in detected cocaine use among youthful arrestees, given that the 1968 birth cohort comprised a declining proportion of the sample over time. Since the 1968 birth cohort turned 21 in 1989, the 1989 sample contained fewer arrestees born in 1968—they were included in the youthful arrestee sample when an arrest preceded the offender's 21st birthday—and samples from 1990 and later contained no one born in 1968. Analysis of quarterly data not presented here indicates that the highest levels of detected cocaine use among youthful arrestees occurred in mid-1989 and decreased dramatically in the fourth quarter of that year.

Table 4 presents results from various postdiction models of the decline in detected cocaine use as a function of various independent variables. The first row shows the observed decline in detected cocaine use from 1987 to 1Q93, for comparison. The second row shows time variation in detected cocaine use postdicted by the combined effects of changes in sample composition and differences across birth cohorts. The combined model closely recreates the observed decline, corroborating the finding from the logistic regression analysis, which suggests that the overall decline does not reflect a reduction or termination of cocaine use.

The last two rows of Table 4 show the decline attributable to changes in sample composition alone and birth cohort alone, respectively. Sample composition alone postdicted a modest decline from 45% in 1987 down to 39% in 1Q93, which is much smaller than the observed decline from 69% to 17%. Hence, changes in policing priorities and/or Drug Use Forecasting practices as measured through the individual attributes included in this analysis can account for, at most, 12% [(45%–39%) ÷ (69%–17%)] of the observed decline in detected cocaine use from 1987 to 1Q93.

On the other hand, the decline postdicted by differences across birth cohorts alone recreates the observed decline as well as the model, including sample composition variables and birth cohort. This further supports the idea that the decline in detected cocaine use resulted primarily from differences in the proportion of youthful arrestees initiating use of cocaine across birth cohorts, and was not owing to changes in sample composition or in cocaine use patterns among members of earlier birth cohorts.

Discussion

Three different statistical analyses with the Drug Use Forecasting–Manhattan data—age-period-cohort analysis, lo-

gistic regression, and postdiction—all strongly suggest that the observed decline in cocaine use among youthful arrestees resulted from a spectacular decline in the proportion of persons who grew up more recently becoming habitual users of cocaine or crack. Arrestees born in 1968 reached age 18 in 1986, the height of the crack epidemic,[26,27] and were the most likely to be detected as cocaine users (78%). Detected cocaine use declined sharply among eight subsequent cohorts of youthful arrestees to 45% among those born in 1971 and a low of 10% among those born in 1975 and 1976. Furthermore, cohorts of arrested youths who initiated cocaine use during the height of the cocaine/crack epidemic during the mid-1980s tend to have continued regular use. Whether new cohorts of youthful arrestees, those born between 1976 and 1979, continue to avoid cocaine and crack before reaching age 21 (and at older ages as well) in 1997 to 2000 remains to be documented. Additional research is also needed to document whether parallel declines in detected cocaine use have been occurring among youthful arrestees in other Drug Use Forecasting cities.

By way of explanation, some ethnographic research suggests that youths reaching their teens in the late 1980s and 1990s saw the ravages of crack smoking and heroin injecting by adults and consciously chose not to use these drugs.[21,28] Alternatively, this dramatic decline may represent a major and important victory for the various efforts such as school-based drug-abuse prevention programs and street sweeps of drug dealers aimed at reducing cocaine abuse in inner-city New York. Additional research is needed to identify the role (if any) of various policy initiatives. Identifying the nature of the most effective programs could help inform future drug abuse prevention policy.

The finding that high-risk, inner-city youths reaching age 18 in the 1990s were dramatically less likely to initiate regular use of cocaine suggests that the cocaine and crack epidemics are ebbing. Widespread use of any particular drug cannot be sustained indefinitely unless large numbers of youths continue to become habitual users. The use of cocaine, and in particular crack, may persist for another 20 or 30 years if those who began using it in the mid-1980s continue regular consumption. Perhaps New York City's crack epidemic will parallel the city's experience with heroin injection, initiation to which was quite common during the 1960s and early 1970s but is undertaken by relatively few young people today.[9] Many persons who began injecting heroin during its period of widest popularity (1963 to 1973) are still injecting it even though they tend to be in their 30s, 40s, and 50s in 1994. An analogous trajectory for crack cocaine would result in substantial numbers of middle-aged crackheads but few youthful crack users in the 2010s. □

Cognitive Impairment and Mortality in Older Community Residents

ABSTRACT

Objectives. Cognitive impairment among the elderly has been linked to mortality in studies of clinical populations. The purpose of this study was to examine the mortality risk associated with cognitive impairment among elderly populations in the community.

Methods. Cognitive impairment and other social and health factors were assessed in 1855 elderly community residents. This sample was reinterviewed periodically to assess changes in health and survival.

Results. At baseline 33% of the sample were mildly impaired and 8% were severely impaired. Across a 48-month observation period the survival probability was .85 for the cognitively unimpaired, .69 for the mildly impaired, and .51 for severely impaired respondents. When adjustments were made for the effects of other health and social covariates, severely impaired persons were twice as likely to die as unimpaired persons. Those who were mildly impaired were also at an increased risk.

Conclusions. Other investigators have found that cognitive impairment is a significant predictor of dementia. We found that it is a significant predictor of mortality as well. Early detection of impaired cognition and attention to associated health problems could improve the quality of life of these older adults and perhaps extend their survival. (*Am J Public Health.* 1994;84:1255–1260)

Introduction

Deficits in cognitive functioning, prevalent among the elderly, are indicators of disease and disability.[1,2] Recent studies among noninstitutionalized populations, employing brief screening tests, indicate that 20% or more of the elderly population may be cognitively impaired. Three or four times as many persons have mild or moderate impairment.[3–5] There is a greater prevalence of cognitive impairment among the older old, those with less education, and minorities.[6–8]

Cognitive impairment is a threat to the quality of life of individuals and their families,[9,10] contributes to increased hospital use,[11,12] and is a risk factor for institutionalization.[13,14] The prevalence of shortened survival among those with dementing disorders[15,16] raises a question about whether milder forms of impairment are associated with mortality. The availability of brief yet reliable measures of cognitive performance[17,18] facilitates such studies.

Most studies linking mortality to cognitive impairment, however,[1] are based on small numbers of elderly individuals with dementing disorders. These studies have employed various measures of cognitive impairment, including detailed clinical assessments. Survival rates have varied by severity of impairment, age, sex, and comorbidity.[19–24]

The few studies of elderly nondemented community residents differ in the representativeness of the samples, measures of cognitive impairment, length of follow-up, and whether other predictors of mortality were controlled.

Two longitudinal studies of nonrepresentative samples of elderly community residents, one of aged twins,[25] the other of very old persons,[26] yielded contrasting findings with regard to the linkage of mortality, impairment, and advancing age. No linkage was found in the study of twins. Increased mortality was associated with age in the study of very old persons later diagnosed as demented.

In a Scottish general practice population, a relative risk of early death of 3.5 was found for elderly cognitively impaired persons compared with nonimpaired persons, but there was no difference in risk of death between those with severe and moderate impairment.[26] These findings resemble those of Jorm et al. in an Australian community sample.[27] Neither study, however, employed multivariate analysis to control for potential risk factors other than age.

Shapiro and Tate recently estimated relative risks from Cox proportional hazards models for a subsample of participants in the Manitoba Longitudinal Study of Aging.[28] In addition to age and sex, cognitive impairment and a diagnosis of dementia contributed significantly to mortality. Potential risk factors including illness, income, and education were not studied, however, possibly because data

Note. Percentages, means, standard deviations, and all other calculations in this and subsequent tables are based on weighted data; totals are unweighted. Weights were applied to adjust for unequal probability sampling.

were limited to physician and hospital records.

Liu et al., studying a subsample from the Framingham Health Study,[29] related performance on a battery of neuropsychological tests to mortality over an 8- to 10-year period. Poor test performance was associated with an increased risk of death even after adjustment for age, education, and illness. The generalizability of these findings may be limited because of the study's high and selective nonparticipation rates. The validity of the test battery as a measure of cognitive impairment is also uncertain.

In this paper we report findings on the association between cognitive impairment and all-cause mortality in a large sample of urban elderly Medicare recipients.[30] Baseline measures of cognitive impairment were assessed as mortality risk factors by means of both univariate and multivariate statistical procedures, with adjustment for the effects of potentially confounding demographic, health, and social variables.

Methods

Sample

Data for this analysis are from personal interviews with 1855 community residents at least 65 years of age who were participants in a longitudinal study of aging and health (Norwood-Montefiore Aging Study [NMAS]).[31] The sample was randomly selected from a list of Medicare beneficiaries living in a neighborhood in the Bronx. Characteristics of the study sample are shown in Table 1. Two thirds were women, more than half were 75 years of age or older, 41% were married, and 44% lived alone. The mean annual income in 1984 was $12 039. Two thirds had private health insurance in addition to Medicare, and nearly 15% received Medicaid. The small proportions of non-Whites and Hispanics reflect the pattern of housing segregation in the study area.

Interviews conducted between July 1984 and March 1985 were the first in a series of semiannual contacts over 3½ years. The response rate to the baseline interview was 73%. Ninety-five percent or more of baseline respondents were reinterviewed in each successive interview wave. Dates and circumstances of death were obtained from proxies, usually family members. Respondents who discontinued participation were recontacted to ascertain survival status. Data were weighted to equalize the representation of elderly people living in households with more than one eligible person.

A 50% sample of nonrespondents was resurveyed 18 months after the health study was under way. Eighty-six percent of these persons, or their proxies, were recontacted. Compared with respondents, more nonrespondents assessed their health as poor or fair. They were more often women, were poorer, and were more likely to live alone. They were not older, however, and interviewers rated nearly equal proportions of both groups as "confused" (7.6% vs 6.6%).[32]

Measures

The Mini-Mental State Exam (MMSE), an instrument widely used to screen for cognitive impairment, was administered at baseline. Developed by Folstein et al., the MMSE assesses signs of dysfunction in orientation, registration, attention, calculation, recall, and language.[33] The MMSE was originally validated with hospitalized patients and subsequently adapted for use in the National Institute of Mental Health's Epidemiological Catchment Area Program.[34] It has been widely employed in studies in this country and abroad.[35–37]

MMSE scores range from 0 to 30. Persons with scores of less than 18 are defined as severely impaired, those with scores of 18 to 23 as mildly impaired, and those with scores of 24 and above as unimpaired. Although the MMSE is an easily administered and reliable tool to identify signs of cognitive impairment, scores do not provide clinical diagnoses.[38] Cognitive impairment may result from a variety of mental conditions including dementia, depression, brain injury, and mental retardation.[39]

Potentially significant mortality risk factors identified in the literature[40–42] were also measured at baseline. Demographic characteristics included age (measured in 5-year groups), sex, and race. Social characteristics included marital status, income (measured in $1000 increments), education (0–8 years vs more), living arrangement (alone or with others), whether any language in addition to English was spoken at home, and receipt of social support (both formal and informal vs neither or only one). Health characteristics included self-assessed health (fair/poor vs good/excellent), number of problems in activities of daily living, number of medical conditions, presence of two or more cardiovascular conditions, symptoms of depression (a Center for Epidemiologic Studies–Depression [CES–D] score less than 18), and visual or hearing problems.

Most of the items defining these variables were constructed from questions taken from the Aging Supplement of the National Health Interview Survey (NHIS) and the National Medical Care Expenditure Survey. Measures of social support and problems in daily living were modified to suit the character of the study sample. Social support was measured according to the frequency and amount of assistance received from family members (informal) or provided by agencies (formal) for personal care, shopping, traveling, money management, and the like, closely paralleling similar items employed by other researchers.[43] Problems in daily living (difficulties in carrying out daily activities) were similar to those used in other current research on functional performance.[44]

Analysis

The analytic strategy was survival analysis, employing Cox proportional hazards models in which the dependent variable, time to death, is predicted by the independent variables and by the MMSE score. This procedure uses all available information about study participants as long as they are followed and is therefore applicable when there are censored observations.

The validity of the proportional hazards assumption was assessed for each predictor by testing whether or not the hazard ratio changed with time. We found

no evidence of an increasing or decreasing trend in the hazard ratios.

Survival curves, by level of cognitive impairment at baseline, were constructed by means of a Kaplan-Meier product limit estimator and tested for homogeneity with the log rank test. The relationship between the independent variables and survival time was assessed with univariate Cox proportional hazards models. Statistically significant variables ($P < .05$) in the univariate analyses were incorporated as predictors in multivariate Cox regression models. Analyses were performed with the fast backward elimination procedure and with predictor variables entered simultaneously. Mortality risk factors for each cognitive impairment subgroup were identified by univariate and multivariate Cox regression analyses. Demographic, health, and social characteristics of the unimpaired and the two impaired subgroups were also compared. Differences among the groups were tested for significance with *t* tests (for continuous variables) or the chi-square test (for dichotomous variables).

Results

Characteristics of Cognitive Impairment Groups

At baseline, 41% of respondents scored as impaired: 33% scored in the mild range (MMSE scores 18–23) and 8% in the severely impaired category (MMSE scores <18). These rates, particularly for mild impairment, are higher than those found in the New Haven and Baltimore Epidemiological Catchment Area sites.[3,4] However, differences in scoring the MMSE (the Epidemiological Catchment Area scoring procedures modified Folstein's original scoring instructions), in the age distributions of the samples, and in administration of the MMSE may account in part for these different rates. The prevalence of impairment for men (39.2%) was not significantly different from that of women (42.1%). Advancing age was associated with severity of impairment.

Health and social characteristics of the unimpaired, mildly impaired, and severely impaired groups at baseline are shown in Table 2. Severely impaired persons compared with their unimpaired peers were older, had more health problems, were poorer, were not as well educated, and were more likely to be women.

Mildly impaired persons differed significantly from their unimpaired peers in age, income, and other socioeconomic characteristics, but not in level of education or in most measures of disability and health. Mildly impaired respondents were younger than their severely impaired peers, tended to be men, had higher levels of income and education, were more often married, less often lived alone, and reported fewer health problems.

TABLE 2—Baseline Characteristics of the Study Sample, by Level of Cognitive Impairment

	Level of Impairment

[c]Problems in performing daily activities.

Survival Probabilities

Sixteen percent of the sample died during a 4-year observation period. These persons represented 11% of the unimpaired, 20% of the mildly impaired, and 38% of the severely impaired persons.

Survival curves for impairment subgroups are shown in Figure 1. Probabilities of survival for severely impaired persons (.51), mildly impaired persons (.69), and unimpaired persons (.85) were all significantly different.

Predictors of Mortality (Time to Death)

The relationship between time to death and each baseline predictor variable, including severe and mild cognitive impairment, was assessed initially by means of a Cox univariate proportional hazards model. Results are shown in Table 3. Regression coefficients for nearly all demographic, social, and health variables were statistically significant. Except for income, each manifested a significant relative risk for shortened survival.

Statistically significant variables were next entered into a multivariate Cox regression model to assess the indepen-

dent contribution of each variable, controlling for the effects of others. Results of the backward elimination procedure are shown in Table 4. The risk ratio was 2.2 for severe impairment and 1.5 for mild impairment. Thus, even when health, demographic, and social factors are controlled, cognitive impairment whether severe or mild, remains an important mortality risk. Other predictors were male sex, receipt of both formal and informal social support, fair or poor self-assessed health, two or more cardiovascular conditions, and advancing age.

Because men and women in this sample differed by marital status and other health and social characteristics, we entered interaction terms for sex and key independent variables in the multivariate models. However, high correlations between these variables and the interaction terms—for example, .59 (age), .76 (problems in daily living), .75 (self-assessed health), and .85 (social support)—precluded their inclusion in the model. We therefore developed multivariate models separately for men and for women. The results of the models, in which a backward elimination procedure was used, are shown in Table 5.

For both men and women, cognitive impairment is a significant risk factor; the risk is 2.0 for men and 2.3 for women for severe impairment. For mild impairment, the risk for both men and women was 1.5. Additional risk factors for men were poor self-assessed health, more problems in daily living, and low income. Additional risk factors for women were receipt of social support and more problems in daily living. Advancing age was a risk factor common to both.

Risk factors predicting mortality for the entire sample or for each sex, however, may differ by level of cognitive impairment, particularly given the differences in health and social characteristics and in mortality risk associated with different levels of impairment. To explore this issue, additional univariate and multivariate regression analyses were performed for each cognitive status subgroup (unimpaired, mildly impaired, and severely impaired). Results of the multivariate analyses, which employed backward elimination procedures, are shown in Table 6.

Advancing age is the only predictor common to all three groups. In addition to age, receipt of both formal and informal social support (a possible proxy for dependency) and only English spoken at home predicted shortened survival for severely impaired respondents. Absent in this subgroup are other health and social predicators.

Among the mildly impaired, less education, poorer health and functional status (more problems in daily living), receipt of both formal and informal support, advancing age, and male sex were risk factors. These same risk factors, except for social support, low education,

and presence of two or more cardiovascular conditions, apply to the unimpaired subgroup.

Discussion

These results indicate that signs of cognitive impairment, both mild and severe, represent a significant threat to the survival of elderly community residents. In this sample, severely impaired persons were more than twice as likely as unimpaired persons to die within 4 years. Mildly impaired persons also had an increased risk for shortened survival, consistent with a recent finding from a Swedish sample.[35] Mortality risks were associated with severe and mild cognitive impairment even when adjustments were made for health and social factors, and the association was evident for men as well as women.

These findings, based on a large community sample, support the link between cognitive impairment and mortality found in the few studies of elderly persons without a diagnosis of dementia. These findings also point to the importance for shortened survival of mild cognitive impairment, a widely prevalent level of dysfunction among elderly persons in the community. Perhaps because there is often no obvious link to a known medical condition, mild impairment has not often been examined in studies of mortality, nor have physicians and others who provide health services to the elderly been encouraged to screen for its presence.[45]

Cognitive impairment may contribute to mortality in different ways for severely and mildly impaired individuals. Its progression may be a marker for the decline in health of those with dementing illness. Mild cognitive impairment may have a more indirect influence on mortality.[46] Deficiencies in language comprehension, in recall, or in other cognitive areas may contribute to failure to seek timely health care, to use recommended treatments or medications, or to recognize signs and symptoms of disease. If cognitive deficits limit educational and vocational achievement, the resulting socioeconomic disadvantage may then lead to poorer health and increased mortality.

Although this study was based on a large and randomly selected sample, the findings may be limited by the characteristics of the population. Compared with 1984 estimates of the US elderly population, the study sample was older, less affluent, and contained more women and more persons living alone. (Comparison data are available on request.) Data on mortality were based on proxy reports and not death certificates. However, information was obtained within 6 months of death, limiting the potential for recall error. Finally, cognitive impairment was measured by a screening instrument rather than a clinical assessment. Despite these potential limitations, the results are consistent with findings from the Manitoba and Framingham studies, even though the studies differ in samples and in measures of cognitive impairment.

Severe and mild impairment may be different conditions with different origins or different points along a continuum of cognitive decline. Although our data did not permit us to investigate this issue, some individuals with mild signs of cognitive dysfunction may have had a disadvantaged social status or poor health early on that may have limited the expression of cognitive capacity or even stunted its development. On the other hand, mild cognitive impairment may also herald the emergence of dementing illness among those who are not disadvantaged. Strategies designed to lessen the impact of cognitive impairment on the functioning of elderly people require diagnosis of the reasons for the impairment.

The prevalence of cognitive impairment among the elderly, particularly mild impairment, coupled with forecasts for increasing numbers of older persons into the next century, points to the need to train health care professionals to recognize this disability and deal with its potentially negative health consequences. □

The US Economic and Social Costs of Alzheimer's Disease Revisited

ABSTRACT

Objectives. An earlier paper estimated the per-case and national incidence costs of Alzheimer's disease for 1983. This paper updates the estimates of costs per case to 1991 and presents new national prevalence estimates of the economic and social costs of the disease.

Methods. All data for the cost estimates were taken from published sources or provided by other researchers.

Results. At midrange values of the estimated cost and epidemiological parameters, the discounted (at 4%) direct and total costs of Alzheimer's disease were $47 581 and $173 932 per case, respectively. The estimated 1991 national direct and total prevalence costs were $20.6 billion and $67.3 billion, respectively. Assuming conservatively that the prevalence of the disease remains constant, the estimated discounted present values of the direct and total costs of all current and future generations of Alzheimer's patients are $536 billion and $1.75 trillion, respectively.

Conclusions. The $536 billion and $1.75 trillion figures are minimum estimates of the long-term dollar losses to the US economy in 1991 caused by Alzheimer's disease. (*Am J Public Health.* 1994;84:1261–1264)

Richard L. Ernst, PhD, and Joel W. Hay, PhD

Introduction

This paper presents per-case and prevalence estimates of the costs of Alzheimer's disease for the year 1991. The data for the estimates were taken from published sources or provided to us by other researchers. In a previous paper, we estimated the costs of this disease for the year 1983.[1] In this revision we have drawn on a newer and more extensive body of findings.

Methods

The methodology used here is discussed in our earlier paper.[1] Briefly, it is assumed that (1) the cost of Alzheimer's disease is an opportunity cost measured apart from the normal costs of living and health care; (2) the stream of costs begins and the patient becomes completely disabled at the time of diagnosis; (3) the patient's annual costs are constant from diagnosis to death; and (4) the stream of the patient's annual costs is discounted to 1991 at a rate of 4%. Finally, because multiple reports of many epidemiological and cost parameters for Alzheimer's disease exist, interval estimates of the disease population and costs were constructed. The point estimates given below are based on midrange estimates of the individual parameters. The details of the estimation procedures are not presented in full but are available from the authors.

Results

The Epidemiology of Alzheimer's Disease

We estimated the prevalence rates of Alzheimer's disease by age and sex for persons 65 and older from data in three US studies.[2–4] Applied to the middle series US population forecast for 1991,[5] our estimates give a prevalence rate for Alzheimer's disease of 0.042 and a total of 1.35 million cases in the population 65 and older. Other reported rates are much higher,[6,7] possibly owing to diagnostic inaccuracies or the inclusion of mild cases.[8,9] The absence of data on the occurrence of this disease in persons under age 65 forced us to estimate the prevalence in this age group. We assumed that the prevalence rate for persons under age 45 is zero and that the fraction of Alzheimer's patients diagnosed before age 65 is the same as that with symptom onset before age 60 (diagnosis lags symptom onset by 3.5 to 5.5 years[10–15]). Based on the age distributions of Alzheimer's patients given in two US reports,[16,17] we estimated the number of patients aged 45 to 64 at 245 000 persons.

We found only one useful US study giving incidence rates of Alzheimer's disease by age and sex,[18] so we added data from Swedish and Israeli studies[19,20] to those results. Our estimated incidence rates yielded 266 000 newly diagnosed US cases of the disease in 1991.

The duration of survival with Alzheimer's disease from symptom onset falls with the patient's age,[16,21] but the effect of age on survival after diagnosis has not been studied. Hence, we assumed that survival after diagnosis is independent of

TABLE 1—Estimated Net Costs of Alzheimer's Disease per Person in 1991 (Midrange Estimates)

Annual (undiscounted) direct costs	
Diagnosis (first year only)	$ 1 450
Nursing home	7 570
Long-term mental hospital	392
Paid home care	3 140
Regular physician care	233
Acute care hospitalization	1 202
Other patient direct costs	0
Caregiver medical care	153
Total direct cost (first year only)	14 140
Total direct cost (second and later years)	12 690
Annual (undiscounted) indirect costs of unpaid home care	20 900
Total cost first year, excluding morbidity and mortality	35 040
Total cost second and later years, excluding morbidity and mortality	33 590
Total discounted direct cost[a]	47 581
Total discounted (direct cost + unpaid caregiver cost)[a]	123 556
Total discounted (direct cost + unpaid caregiver cost + disability and premature mortality cost)[a]	173 932

[a]Assuming a 4% annual discount rate and survival of 3.3 years for men, 4.3 years for women.

age. We assumed further that women live 4.3 years after diagnosis and men live 3.3 years—the averages of disease durations reported in two studies of Alzheimer's.[14,22]

The Costs of Alzheimer's Disease

Alzheimer's patients are cared for in the community, in nursing homes, and in mental hospitals, but the number of patients treated at each of these locations is unknown. We therefore estimated the number of patients living at each location before estimating the costs of care.

Nursing home costs. Extrapolating from data in the National Nursing Home Survey of 1985,[23] we estimated the average daily nursing home census at 1.743 million persons in 1991. Unfortunately, data on the percentage of residents with Alzheimer's disease vary widely. Estimates from the Nursing Home Survey vary from 6.3% to 9.4%,[23,24] but a national survey of Medicaid nursing home residents found that 23.5% were diagnosed with the disease.[25] The Nursing Home Survey data themselves indicated that 43.3% of all residents in 1985 were diagnosed with organic brain syndrome, and, assuming that 60% to 70% of organic brain syndrome is due to Alzheimer's disease,[26-29] this estimate implies a range of 26.0% to 30.3% of all residents with Alzheimer's. Accordingly, we determined the percentage of Alzheimer's patients in nursing homes in 1991 to be 10% to 30%, the midrange of which gave an estimate of 349 000 residents with the disease.

Based on our estimate of nursing home average daily census, national nursing home spending in 1991[30] amounted to $34 400 per annual resident. Since it is claimed that the cost for a demented patient is 12% to 20% higher than the average,[31,32] we put the gross annual nursing home cost for an Alzheimer's patient at $38 500 to $41 300. We estimated normal annual usage of nursing homes by persons aged 45 and older (the ratio of residents without Alzheimer's disease to the population at risk) at 0.016 to 0.020 years, and calculated the normal annual cost of food and shelter to be $4700 per person in 1991.[33] Hence, the estimated annual net cost of Alzheimer's nursing home care was $7570 per patient overall.

Mental hospital costs. We estimated the number of mental hospital patients in 1991 (185 000 persons) by projecting an annual time series of average daily censuses.[34] The number of Alzheimer's patients living in mental hospitals was estimated from data in two studies on residents with organic brain syndrome or probable Alzheimer's disease,[34,35] and was reckoned at 4000 to 7000 in 1991. The estimated gross annual cost of mental hospitalization was $113 600 per patient with Alzheimer's—obtained by inflating the overall average cost per patient in 1988[34] to 1991 levels by the medical care component of the consumer price index. Normal mental hospital usage was determined to be negligible so that, apart from normal living costs, the estimate of annual mental hospital costs was $392 per person with Alzheimer's disease.

The cost of community care. Community care refers both to nonmedical services provided to patients with Alzheimer's disease and to respite services for caregivers. The number of Alzheimer's patients living in the community (the Alzheimer's population less the number of institutionalized patients) was estimated at 1.240 million persons. Based on results from nine studies of community-dwelling demented or mentally impaired patients, we estimated the weekly number of paid and unpaid caregiver hours at 7.9 and 52.5, respectively.[31,36-44] Paid caregiver time was priced at $9.38 (the rate for home health care workers in 1991[45]), but that figure is at least 10% lower than the hourly cost (expressed in 1991 dollars) reported in three studies of caregiving for demented persons,[31,44,46] and it also excludes home care agency costs. We therefore set the hourly rate at $9.40 to $10.30 and assumed that the opportunity cost of unpaid caregiver time was the same. The resulting estimates of gross annual paid and unpaid caregiver time were $4050 and $26 900 for the home-dwelling patient. Because the normal amount of in-home caregiver time is negligible,[46-50] the annual net costs of paid and unpaid community care were $3150 and $20 900 per Alzheimer's patient overall.

Physicians' services: diagnosis. Diagnostic costs were estimated at $1450 per patient in 1991. The figure is our 1983 estimate (based on 1987 technology) of the cost inflated by the medical services component of the consumer price index.

Physicians' services: regular care. In five studies it has been reported that (mostly) elderly patients with Alzheimer's disease or dementia use 0.8 to 2.4 times as many physician visits as the average for all persons 65 and older (6 to 19.5 visits per year[36,42-44,48] vs 8.2 visits[51]). If the same multiple holds regardless of age, then patients with Alzheimer's disease average from 1.3 fewer to 9.2 more visits annually than all persons aged 45 and older (6.6 in 1990[51]). To cost these visits, we drew on 1990 physician survey data from the American Medical Association[52,53] inflated to 1991 price levels, and we estimated physicians' average revenue per visit at $59 in 1991. The (midrange) estimated annual net cost of outpatient physician services was therefore $233 per Alzheimer's patient in 1991.

Hospitalization. In various studies, persons with Alzheimer's disease or other mental impairment used the hospital 30% to 200% more than normal controls or the national average,[36,42,43,54] roughly the same as the normal population,[31,55] or less than normal persons.[56] Given these contradictory findings, we assumed that the average Alzheimer's patient used 0 to 200% more hospital days annually than a normal person aged 45 or older (1.37 days in 1990[51]). This would have meant an additional 0 to 2.7 inpatient days priced (apart from normal daily living costs) at $831 each,[57] plus one physician visit per day costing $59. The total net cost of hospital use was $1202 per patient in 1991.

Other direct costs. Other costs of Alzheimer's disease mentioned in the literature are associated with prescribed drugs, transportation, and health care visits to (or by) nonphysician providers,[31,36,42,43,58] but owing to scanty or contradictory evidence, we assumed that these costs were zero.

Caregiver costs. Caregiving for Alzheimer's disease causes economic costs only when it leads to an abnormal use or loss of economic resources. The costs of respite services and caregivers' loss of productive time have been counted in the costs of home care, but another cost occurs if the caregiver uses an abnormal amount of medical care. According to reports, caregivers of demented persons use 46% more physician visits and 71% more prescribed drugs than control subjects, and are more likely to be hospitalized as well[59,60]; however, it has also been found that physician usage and sick days are essentially the same for Alzheimer's caregivers and matched control subjects.[38] Hence, we estimated additional physician costs at 0 to $224, drug costs at 0 to $170 per caregiver-year (the upper bound is 0.71 times national per capita drug purchases in 1991[43]), and hospital costs at zero. Estimated net caregiver costs were $153 per Alzheimer's patient overall.

Loss of lifetime earnings owing to disability and premature mortality. The loss of the Alzheimer's patient's labor income dates from diagnosis and covers the period of a normal life expectancy.[61] We estimated lifetime earnings from an age-income profile provided to us by Dorothy Rice and her associates. The income streams were discounted at 4% and aggregated over all persons diagnosed with the disease in 1991. The earnings loss was estimated at about $50 380 per person.

Total costs. The midrange estimates of annual costs per Alzheimer's patient and costs per case are summarized in Table 1. The annual prevalence cost of the disease is the size of the Alzheimer's population times the average annual cost per patient. At midrange values of the parameters, estimated direct prevalence costs were $20.6 billion in 1991. Total annual unpaid caregiver costs were $33.3 billion, and the present value of the costs of disability and premature mortality were $13.4 billion for persons first diagnosed in 1991. Altogether, the 1991 annual prevalence costs of Alzheimer's disease were $67.3 billion. Supposing conservatively that the Alzheimer's population is constant over time, the present values of the annual direct and total costs of all future generations of Alzheimer's patients beginning in 1991 are about $536 billion and $1.75 trillion, respectively. These figures are the estimated discounted direct and total present values of resources that society will consume or lose because of this disease beginning in 1991.

Conclusion

The costs of caring for a patient with Alzheimer's disease, as reported here, are higher than those (for 1983) given in our earlier paper owing partly to price inflation and partly to new assumptions drawn from the literature. Adjusted to 1990/91 price levels, other (data-based) estimates of the annual direct and unpaid caregiver costs of Alzheimer's disease or mental impairment range from about $12 000 to $47 000 per patient.[31,32,36,41] Our figures ($33 600 to $35 000) fall toward the middle of this range, but comparisons between them and the other estimates are tenuous because of differences in methodology. Nevertheless, all the estimates indicate that the major economic burden of Alzheimer's is the cost of long-term home and institutional care. For home-dwelling patients, most of this burden—nearly $31 000 per person in 1991—is borne indirectly by caregivers, but much of the cost of institutionalization falls on the public at large. Assuming that 20% of all nursing home residents had Alzheimers, Medicaid spent $5.7 billion[30] in 1991 on these patients. To add some perspective on this cost, we estimate that the total medical cost of acquired immunodeficiency syndrome (AIDS) was no more than $4.2 billion in 1991 (assuming 77 000 cases[62] and a cost per case of $50 000 to $55 000[63]). Thus, even the Medicaid cost of Alzheimer's probably exceeds the total medical cost of a more publicized disease like AIDS. Clearly, the discovery of palliatives or cures for Alzheimer's disease would greatly benefit society as a whole. □

The Burden and Outcomes Associated with Dehydration among US Elderly, 1991

Joan L. Warren, PhD, W. Edward Bacon, PhD, MPH, Tamara Harris, MD, MS, A. Marshall McBean, MD, MSc, Daniel J. Foley, MS, and Caroline Phillips, MS

ABSTRACT

Objectives. Dehydration has been underappreciated as a cause of hospitalization and increased hospital-associated mortality in older people. This study used national data to analyze the burden and outcomes following hospitalizations with dehydration in the elderly.

Methods. Data from 1991 Medicare files were used to calculate rates of hospitalization with dehydration, to examine demographic characteristics and concomitant diagnoses associated with dehydration, and to analyze the contribution of dehydration to mortality.

Results. In 1991, 6.7% (731 695) of Medicare hospitalizations had dehydration listed as one of the five reported diagnoses, a rate of 236.2/10 000 elderly Medicare beneficiaries. In 1991, Medicare reimbursed over $446 million for hospitalizations with dehydration as the principal diagnosis. Older people, men, and Blacks had elevated risks for hospitalization with dehydration. Acute infections, such as pneumonia and urinary tract infections, were frequent concomitant diagnoses. About 50% of elderly Medicare beneficiaries hospitalized with dehydration died within a year of admission.

Conclusions. Hospitalization of elderly people with dehydration is a serious and costly medical problem. Attention should be focused on understanding predisposing factors and devising strategies for prevention. (*Am J Public Health.* 1994;84:1265–1269)

Introduction

Dehydration is a common condition in the elderly, and, in 1991, dehydration was 1 of the 10 most frequent diagnoses reported for Medicare hospitalizations (Health Care Financing Administration [HCFA], unpublished data). Dehydration has been reported previously as the reason for hospitalization in 0.65% and 2.25% of all admissions to two hospitals.[1] In a case series of 15 187 hospital admissions in a single hospital, 1.1% of patients 60 years of age and older were found to have hypernatremia.[2] These studies, from a limited number of hospitals, highlight the lack of published information on hospitalizations with dehydration, including the incidence of dehydration in the elderly population, patterns of mortality, and concomitant health conditions. As the number of elderly people increases—especially the oldest old, who appear to be more prone to dehydration[3–5]—the importance of dehydration as a medical condition is likely to increase. Examination of national data on hospitalizations among the elderly can help delineate the extent of the burden resulting from dehydration and promote the need for strategies to prevent morbidity, mortality, and costs associated with this condition.

In this paper, we examine hospitalizations with dehydration among people 65 years of age and older. We first examine the burden of dehydration in the elderly by presenting the rates of hospitalizations with dehydration in 1991 as well as identifying specific demographic groups at risk of hospitalization for dehydration and at risk of dying within 30 days of admission. We then explore areas for potential interventions that might lessen the impact of dehydration. This analysis includes the identification of concomitant diagnoses that are reported frequently for hospitalizations with dehydration, which may improve understanding of the causes of this condition. In addition, we estimate the effect of dehydration on mortality by comparing, for 10 groups of principal diagnoses, early and late mortality following hospitalizations with and without dehydration as a concomitant diagnosis.

Methods

Data for this project were obtained from the Medicare Provider Analysis and Review (MEDPAR) files maintained by HCFA. These files, which are available from 1984 to the present, contain summarized records of all claims submitted by hospitals for services provided to Medicare beneficiaries. For each hospitalization, the MEDPAR record contains information about the beneficiary's age, race, and sex; up to five diagnoses classified according to the *International Classification of Diseases, 9th Revision, Clinical*

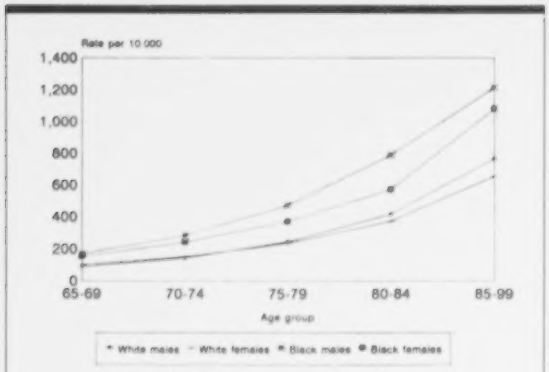

FIGURE 1—Rate of hospitalization with any listed diagnosis of dehydration per 10 000 elderly Medicare beneficiaries, 1991.

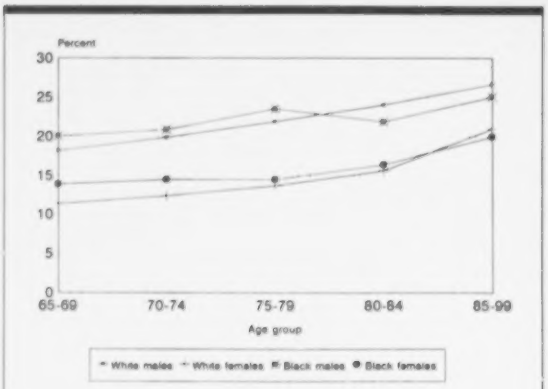

FIGURE 2—Age-, race-, and sex-specific percentages of patients dying within 30 days of admission, among elderly Medicare beneficiaries hospitalized with a diagnosis of dehydration, 1991.

Modification (ICD-9-CM)[6]; the amount reimbursed to the hospital by Medicare and the dates of admission and discharge; and the date of death (reported by the Social Security Administration) if death occurred within 2 years after the year of hospitalization.

Dehydration is a condition with multiple causes,[1,7-10] and the term is commonly used to reflect several related physiological states based on an imbalance between intake and loss of fluid and the accompanying sodium status.[4,10,11] The present study included as cases all hospitalizations involving an ICD-9-CM code for volume depletion (276.5), regardless of sodium status, since in most cases sodium status was not reported. Medicare beneficiaries who were hospitalized in 1991 with dehydration were identified from a review of a 20% random sample of all hospitalizations. All records with an ICD-9-CM diagnosis of volume depletion appearing as the principal or as a concomitant diagnosis were selected. (The principal diagnosis is the diagnosis that, after thorough review, is believed by the physician to be the cause for the hospitalization.) We use the phrase "hospitalization with dehydration" to refer to cases with dehydration as one of the five diagnoses; "hospitalization for dehydration" refers to those with dehydration as the principal diagnosis. We limited our analysis to Black and White Medicare beneficiaries who were 65 to 99 years of age and resided in 1 of the 50 states or the District of Columbia. We excluded the estimated 5% to 6% of Medicare beneficiaries who were enrolled in a health maintenance organization (HMO) at the time of hospitalization because Medicare utilization records for HMO enrollees are incomplete.

The rate of hospitalization with dehydration in 1991 was calculated per 10 000 elderly beneficiaries enrolled in Medicare's hospitalization insurance program (Part A) as of July 1 of that year. Preliminary data showed an interaction effect between increasing age and sex on rates of hospitalization with dehydration; therefore, we calculated age-, race-, and sex-specific rates. Comparisons between all possible combinations of strata were made (i.e., rates for age between each race–sex group, rates for sex between each race–age group, and rates for race between each sex–age group). The method described by Kahn and Sempos[12] was used to calculate the relative risk and surrounding 95% confidence interval for each comparison. The respective reference groups for each of the comparisons were individuals 65 to 69 years of age, men, and Whites. The proportion of people who died within 30 days of being admitted to the hospital with dehydration was calculated for each age, race, and sex group, and comparisons were made as described above.

To determine the cost to Medicare, we totaled the amount reimbursed in 1991 by HCFA for hospitalizations with dehydration as the principal diagnosis. The average cost per hospitalization was determined from the median amount reimbursed by HCFA per hospitalization for dehydration as the principal diagnosis. We were unable to determine from these data the additional costs to Medicare for cases involving dehydration as a concomitant diagnosis.

We used the MEDPAR data to examine all diagnoses reported for hospitalizations with dehydration in 1991. To facilitate interpretability of the data, diagnoses were assigned to 1 of 10 categories based on ICD-9-CM codes. (The specific codes included in each diagnosis category are listed in the Appendix.) The frequency at which each diagnosis category occurred for hospitalizations with dehydration is presented. Because each record contains up to five diagnoses, more than one diagnosis category may be present during a single hospitalization.

To examine the contribution of dehydration to mortality for selected principal diagnoses, death rates after hospitalization with a concomitant diagnosis of dehydration were compared with death rates after hospitalization with no concomitant diagnosis of dehydration. The 10 previously described diagnosis categories were used in classifying principal diagnoses. Hospitalizations without a concomitant diagnosis of dehydration were obtained from a 20% random sample of hospitalization records from 1991. For this comparison, the mortality rates were adjusted for race, sex, and age by the direct method, with the total number of beneficiaries hospitalized in 1991 as the standard population. Relative risks and surrounding 95% confidence intervals were calculated as described previously. Deaths occurring within 30 days of admission were considered as early mortality;

TABLE 1—Frequency of Selected Diagnoses Reported for Hospitalizations with Any Listed Diagnosis of Dehydration among Elderly Medicare Beneficiaries, 1991

Diagnosis Category[a]	Sample, %
Respiratory illness	28.2
Urinary system infections	24.9
Cardiac	21.8
Frailty	20.3
Other metabolic disorders	18.9
Other gastrointestinal conditions	18.8
Cancer	15.7
Diabetes	12.0
Gastroenteritis	10.4
Sepsis	7.1

[a]Diagnosis appears as one of five reported to Medicare; see Appendix for specific codes for each category.

TABLE 2—Early and Late Mortality Rates for Selected Principal Diagnosis Categories among Elderly Medicare Beneficiaries Hospitalized with and without a Concomitant Diagnosis of Dehydration, 1991

Principal Diagnosis Category	30-Day Post-admission Mortality Rate[a]	Relative Risk (95% Confidence Interval)	31- to 365-Day Post-admission Mortality Rate[a]	Relative Risk (95% Confidence Interval)
Dehydration	17.4	... ...	30.6	... ...

Without dehydration[b]	7.9	1.00 ...	17.3	1.00 ...
With dehydration	11.1	1.41 (1.20, 1.65)	24.4	1.41 (1.27, 1.57)

[a]Per 100 hospitalizations. Adjusted for age, race, and sex.
[b]Reference group.

those occurring between 31 and 365 days after admission were considered as late mortality.

Results

In 1991, the rate of hospitalization per 10 000 elderly Medicare beneficiaries was 236.2 admissions with any listed diagnosis of dehydration and 49.7 admissions for dehydration as a principal diagnosis. Of the more than 10 million hospitalizations involving elderly Medicare beneficiaries during that year, 6.7% (731 695 hospitalizations) had a diagnosis of dehydration in any position and 1.4% (146 960 hospitalizations) had dehydration listed as the principal diagnosis.

There were significant differences in the rate of hospitalization with dehydration by age, race, and sex (Figure 1). Increasing age was a major factor in risk of admission with dehydration, with people 85 to 99 years of age more than 6 times more likely to be hospitalized for dehydration than those 65 to 69 years of age. At each age, Blacks were 1.5 to 2 times more likely than Whites to be hospitalized with dehydration. Within race, men were more likely to be admitted with dehydration than were women, except for Whites 65 to 79 years of age.

Overall, more than 18% of patients died within 30 days of hospitalization with dehydration. Mortality rates increased with age, even among the young old (those 65 to 74 years of age), and 30-day postadmission mortality was about 12% for women and 18% for men. For each age–race stratum, the proportion of men dying was 26% to 63% higher than that of women (Figure 2). Comparison of data by race suggests that, for both sexes, the percentage of Blacks dying was higher up to 79 years of age but lower for the 85- to 99-year age range. The greatest difference between the race–sex groups was for Black women 65 to 69 years old, who had mortality rates 22% higher than White women in the same age group.

The total amount reimbursed by HCFA to hospitals for treatment of beneficiaries hospitalized for dehydration as the principal diagnosis was more than $446 million. The median cost per hospitalization for dehydration as the principal diagnosis was $2942.

A review of all diagnoses reported for hospitalizations with dehydration showed that a large number of patients with dehydration also had acute infections: 28.2% had a respiratory illness, 24.9% had a diagnosis of urinary system infection, 10.4% had a diagnosis of gastroenteritis, and 7.1% had a diagnosis of sepsis (Table 1). Chronic conditions such as frailty, cancer, and diabetes occurred in 20.3%, 15.7%, and 12.0% of hospitalizations, respectively.

Among people hospitalized with a principal diagnosis of dehydration, almost half died within a year of admission, with 17.4% dying within 30 days of admission

and an additional 30.6% dying in the remaining 11 months of the year (Table 2). For hospitalizations with dehydration as a concomitant condition, there was considerable variation in mortality based on the principal diagnosis. Comparison of mortality rates by principal diagnosis for hospitalizations with and without a concomitant diagnosis of dehydration showed that, for each principal diagnosis, hospitalizations with a concomitant diagnosis of dehydration involved significantly higher mortality for both the early and later periods, with the exception of deaths within 30 days of hospitalization for gastroenteritis.

Discussion

These data demonstrate that dehydration in the elderly is a serious, frequent, and costly medical problem that may not have been fully recognized to date. Older people, men, and Blacks are more likely to be hospitalized for dehydration. Hospitalization resulting from dehydration is associated with an increased risk of death, particularly for older men. In 1991, Medicare payments were more than $446 million for beneficiaries hospitalized with dehydration as a principal diagnosis. This figure does not include costs of treatment for the entire episode of care (physician visits, home health or skilled nursing care), care provided to beneficiaries enrolled in an HMO, or additional costs to Medicare for 584 735 non-HMO hospitalizations that involved dehydration as a complicating condition.

In this study, the 1.4% of hospitalizations with dehydration as the principal diagnosis is comparable to what has been reported in previous research.[1,2] Unlike prior researchers, we reviewed all diagnoses reported for each hospitalization. We found that 6.7% of all hospitalizations had dehydration listed as one of five diagnoses. This finding suggests that all diagnoses reported during a hospitalization should be reviewed to assess the full extent of dehydration as a problem among hospitalized elderly people.

In the present study, of people admitted with a principal diagnosis of dehydration, the percentage dying within 30 days of admission—17.42—was lower than the 46% to 48% reported for hospitalizations for hypernatremic dehydration.[3,13] The variation in mortality found between the present and previous studies may reflect differences in case definition or special characteristics of those with hypernatremia. However, previous studies have attributed high mortality rates not to the level of hypernatremia but to the significant underlying disease.[3,13] To address this issue, we stratified by principal diagnosis. From this stratification, it appears that the risk of mortality after hospitalization with dehydration varies considerably depending on principal diagnosis. However, for each principal diagnosis, the concomitant diagnosis of dehydration was associated with an increased risk of death.

The high rates of mortality suggest that hospitalization with dehydration should be considered a marker for an increased risk of death within the next year. We examined another common condition in the elderly, hip fracture, that has a high post-admission mortality rate and is often considered to place the person at increased risk of death within the year following the event. By comparison, mortality within 30 days of admission has been reported as 6.4% of hospitalizations with hip fracture[14] and 17.4% of hospitalizations with dehydration. Within 1 year, 20% of patients with hip fractures died,[15] in comparison with more than 47% of those with dehydration.

Recognizing the incidence, risks, and costs associated with dehydration raises the need for strategies to prevent the condition. Of the underlying diseases likely to cause dehydration, some appear preventable. Respiratory illnesses, which were diagnosed in more than 28% of those hospitalized with dehydration, could possibly be prevented or reduced by influenza and pneumococcal vaccination.[16,17] Yet, it is currently estimated that only 30% to 41% of individuals over age 65 are immunized annually against influenza, and only 14% to 20% have received a pneumococcal vaccination.[18,19] Other infectious diseases, although not as amenable to prevention, should be recognized as potential predisposing factors for dehydration among older people. For instance, dehydration associated with gastroenteritis may be prevented by prompt recognition of the gastroenteritis and intervention through fluid orders, including the use of oral rehydration or administration of intravenous fluids. Efforts to prevent dehydration should be directed toward educating elderly patients, especially those living alone, regarding the risk of dehydration and the need to maintain adequate oral intake during periods of acute illness. Nursing personnel should also be made aware of the importance of monitoring fluid intake in elderly patients in hospitals and nursing homes.

There are several limitations to our study. We cannot determine from the data whether the dehydration occurred prior to or during the hospitalization. In addition, we cannot ascertain from the Medicare data the clinical treatment that might have influenced dehydration outcomes (e.g., rapid rates of rehydration that might increase mortality).[3] Administrative data do not provide information on the underlying health status of people hospitalized with dehydration. While it appears that acute illness is associated with dehydration, it may be that these individuals also have chronic medical conditions that influence the risk and outcomes of dehydration.

The accuracy of secondary data in measuring the extent of dehydration may be questioned. However, the MEDPAR data used in the present study were validated from a second source, the National Hospital Discharge Survey. This survey, conducted annually by the National Center for Health Statistics (NCHS), includes data abstracted from the medical records of a representative sample of discharges from non-federal short-stay hospitals in the United States.[20] The survey data are subject to field quality checks for validity and reliability. For the years 1984 to 1991, a comparison of the data available from the survey and from MEDPAR revealed that the population-based rates of dehydration observed from both sources were essentially the same (HCFA and NCHS, unpublished data, 1984–1991).

In conclusion, this study provides the first national estimates that demonstrate the extent to which dehydration is a significant cause of morbidity, mortality, and health care costs in the elderly. Hospitalizations with dehydration are associated with acute illness, which suggests that some cases of dehydration may be preventable. Investigations in the clinical setting of specific diseases associated with dehydration may yield additional preventive strategies and sources of cost savings. Furthermore, rates of mortality after hospitalizations with dehydration both as a principal and as a concomitant diagnosis are high. People hospitalized with dehydration should be considered at increased risk for dying within the year following admission. Recognition by health care providers of the extent that dehydration is a problem in the elderly, prevention of the underlying causes, and prompt treatment of the early stages of dehydration may reduce the morbidity, mortality, and costs resulting from this condition. □

APPENDIX—ICD-9-CM Codes Used to Classify Diagnoses for Medicare Beneficiaries Hospitalized with Dehydration

Diagnosis Category	ICD-9-CM Code(s)
Dehydration	276.5
Respiratory illness	
Acute bronchitis	466.0–466.1
Chronic lung disease	490.0–496
Pneumonia and influenza	480–487.8
Gastroenteritis	003.0, 008.5, 008.6, 008.8, 009.0–009.3, 536.2, 558.9, 787.0
Other gastrointestinal conditions	
Abdominal pain	789.0
Cholelithiasis	574.0–574.51
Diseases of the esophagus	530.0–530.9
Diverticulitis	562.01, 562.03, 562.11, 562.13
Diverticulosis	562.00, 562.02, 562.10, 562.12
Gastritis	535.0–535.6
Gastrointestinal hemorrhage	578.0–578.9
Idiopathic proctocolitis	556
Intestinal obstruction	560.8–560.99
Pancreatitis	577.0–577.9
Paralytic ileus	560.1
Regional enteritis	555.0–555.9
Urinary system infection	
Kidney infection	590.0–590.9
Urinary tract infection	595.0, 595.9, 599.0
Cancer	140.0–208.9
Sepsis	038.0–038.9
Cardiac	
Acute myocardial infarction	410.0–410.92
Angina	411.1
Arrhythmias	427.0–427.32, 427.6–427.9
Congestive heart failure	428.0–428.9
Frailty	
Aspiration pneumonia	507.0
Decibitus ulcer	707.0
Dementia	290.0–290.9, 331.0, 331.2, 797
Impaction	560.3–560.39
Malnourishment	263.0–263.9, 262, 783.0, 799.4, 260, 261
Diabetes	250.0–250.91
Other metabolic disorders	
Diabetes insipidus	253.5, 588.1
Hyperkalemia	276.7
Hypernatremia	276.0
Hypoglycemia	251.2
Hypokalemia	276.8
Hyponatremia	276.1
Hypotension	458.0–458.9
Inappropriate antidiuretic hormone (SIADH)	253.6

The Groningen Activity Restriction Scale for Measuring Disability: Its Utility in International Comparisons

ABSTRACT

Objectives. The Groningen Activity Restriction Scale (GARS) is a non–disease-specific instrument to measure disability in activities of daily living (ADL) and instrumental activities of daily living (IADL). It was developed in studies of Dutch samples consisting of elderly or chronically ill people. The psychometric properties of the GARS demonstrated in these studies were highly satisfactory. This paper addresses the psychometric properties of the GARS across countries.

Methods. Data of 623 patients with recently diagnosed rheumatoid arthritis from four European countries were analyzed by means of a principal components analysis and a Mokken scale analysis for polychotomous items.

Results. The results of the analyses were highly satisfactory: there was one strong and reliable general factor representing one underlying dimension of disability in ADL and IADL, and there was a clear hierarchical ordering of the items included in the GARS. The validity of the GARS was strongly suggested by the pattern of associations of the GARS with age, sex, and other existing health status measures.

Conclusions. The psychometric characteristics of the GARS, which measures disability in ADL and IADL simultaneously, make this instrument very useful for comparative research across countries. (*Am J Public Health.* 1994;84:1270–1273)

Introduction

Rheumatoid arthritis is a chronic disease with a varying clinical course. Therefore, measures of the "objective" severity of the disease are always time-dependent. The paroxysmal character of the disease makes it fairly unpredictable for patients themselves and for their significant others. Part of the burden of rheumatoid arthritis is caused by this varying and unpredictable course.[1]

Sooner or later, patients with rheumatoid arthritis experience impairments and "social disability," that is, "dysfunctioning in a social role or in some aspect of social behavior."[2] The relevance of the behavioral consequences of a disease has often been stressed because these consequences are of crucial importance for the daily functioning of the individuals involved.[3] In this article we will confine ourselves to restrictions regarding certain activities and tasks, that is, activities of daily living (ADL) and instrumental activities of daily living (IADL), sometimes referred to as "housekeeping activities of daily living."[4]

ADL functions are essential for an individual's self-care (e.g., washing or dressing oneself), whereas IADL functions are more concerned with self-reliant functioning in a given environment (e.g., shopping, preparing meals).[5] The distinction between these two groups of activities is mainly a consequence of "institutional thinking." In many countries, the delivery of care with respect to these two groups of activities is provided by different professions or agencies (sometimes combined with different types of financing); therefore, these two groups of activities have been distinguished and measured separately.[6,7] From the perspective of the patient, however, ADL functions are no less "instrumental" than IADL functions.

Partly on the basis of existing instruments, Kempen and Suurmeijer developed the Groningen Activity Restriction Scale (GARS).[8,9] The instrument was developed to measure both ADL and IADL disability in community-based studies with respect to the aid and services provided by professional home help and district nursing agencies. The patient's physical condition, of course, plays an important role in this respect, but the patient's personality and contextual and interactional variables may be important as well in the "appraisal of one's abilities."[9,10]

The GARS has been applied in several studies in the Netherlands.[11] It has proven to be a very useful instrument: it makes it possible to (1) more precisely describe the severity of the disablement caused by several chronic conditions, (2) establish changes in disablement over

time, (3) differentiate more accurately between degrees of disability, and (4) improve the assessment of the need for professional care.

In this article we use data from an international longitudinal study of patients recently diagnosed with rheumatoid arthritis (European Research on Incapacitating Diseases and Social Support [EURIDISS][12]) to analyze the overall psychometric properties of the GARS across countries. More specifically, we test the unidimensionality and hierarchical order of the scale items and explore the scale's construct validity.

Methods

Sampling Procedures

The criteria for inclusion in the EURIDISS study have been published elsewhere.[12] By the end of November 1992, data had been collected on a total of 630 patients with rheumatoid arthritis: 116 French, 292 Dutch, 124 Norwegian, and 98 Swedish patients. The nonresponse rate varied from 12% (the Netherlands) to 30% (France). The patients' mean age was 52 years; mean disease duration was 2.6 years. Thirty-one percent of the patients were men and 69% were women. Because of incomplete data, 7 of these respondents were omitted from the analysis.

Description of the Groningen Activity Restriction Scale (GARS)

The 18 GARS items and five response categories are presented in Table 1. The items refer to what respondents are *able* to do and not to their actual performance, which is a very important distinction.[13] When an item refers to more than one activity (e.g., item 5), the activity causing the greatest problems to the patient determines the response.

Statistical Analysis

In the analyses, the two most extreme responses (4 and 5) were combined, partly because response 5 was chosen by only a few patients. Consequently, sum scores could vary from 18 (not disabled) through 72 (severely disabled).

A principal components analysis was carried out on the scale items, both for the countries separately and for the total sample. Next, reliability figures (Cronbach's alpha[14] or rho[15]) were calculated.

The hierarchical order of the ADL and IADL items was tested with the Mokken scale analysis for polychotomous items (MSP).[15,16] MSP is a probabilistic (nonparametric) extension of Guttman scale analysis[17] that can handle three or more rank-ordered response categories per item. The program calculates three different scalability coefficients: H_i for individual items, H_{ij} for item pairs, and H for a set of items as a whole. For a set of items to be accepted as a scale, it is required that all H_i's be greater than .00 and all H_{ij}'s be greater than or equal to .30. In that case H will be greater than or equal to .30. The H coefficient refers to the strength of the scale as a whole: if H is from .30 up to .40, the scale is "weak"; if H is from .40 up to .50, the scale is "moderately strong"; if H is equal to or greater than .50, the scale is "strong."

Analyses of variance were carried out to test for differences in GARS scores across countries, age, and sex, and the construct validity of the GARS and its component parts was explored.

TABLE 1—Items and Response Categories of the Groningen Activity Restriction Scale (GARS)

Response categories for each item
1. Yes, I can do it fully independently without any difficulty.
2. Yes, I can do it fully independently but with some difficulty.
3. Yes, I can do it fully independently but with great difficulty.
4. No, I cannot do it fully independently, I can only do it with someone's help.
5. No, I cannot do it at all, I need complete help.

Activities of daily living (ADL)
1. Can you, fully independently, dress yourself?
2. Can you, fully independently, get in and out of bed?
3. Can you, fully independently, stand up from sitting in a chair?
4. Can you, fully independently, wash your face and hands?
5. Can you, fully independently, wash and dry your whole body?
6. Can you, fully independently, get on and off the toilet?
7. Can you, fully independently, feed yourself?
8. Can you, fully independently, get around in the house (if necessary, with a cane)?
9. Can you, fully independently, go up and down the stairs?
10. Can you, fully independently, walk outdoors (if necessary, with a cane)?
11. Can you, fully independently, take care of your feet and toenails?

Instrumental activities of daily living (IADL)
12. Can you, fully independently, prepare breakfast or lunch?
13. Can you, fully independently, prepare dinner?
14. Can you, fully independently, do "light" household activities (for example, dusting and tidying up)?
15. Can you, fully independently, do "heavy" household activities (for example, mopping, cleaning the windows, and vacuuming)?
16. Can you, fully independently, wash and iron your clothes?
17. Can you, fully independently, make the beds?
18. Can you, fully independently, do the shopping?

Results

Results of Factor Analyses

From the principal components analysis on the GARS items, both for the countries separately and for the total sample, it appeared that the first factor was a very strong and reliable one. The sum score of the GARS was directly derived from the raw (i.e., unweighted) scores. The correlation between this sum score and the factor scores (i.e., weighted item scores) was .9938. Therefore, the raw scores can be used when calculating the GARS score. A scree plot of the eigenvalues of the extracted components confirmed the assumption of one underlying dimension: after the first general component (eigenvalue = 8.71), there was a clear "elbow" in the curve of the consecutive eigenvalues.

As mentioned before, the ADL and IADL items are often considered to indicate two specific types of disability. Therefore, we repeated the same analyses as before for the 11 ADL and 7 IADL items separately, for the countries separately and for the total sample. It appeared that both the ADL and IADL items form one strong and reliable general factor; no other factors with an eigenvalue of 1.00 or more could be extracted.

The mean GARS score (range = 29.2–32.6), as well as the mean ADL and IADL scores (range = 15.8– 17.4 and 13.2–15.2, respectively), differed some-

TABLE 2—Correlations of the GARS and ADL and IADL Scales with the Physical Mobility Subscale from the Nottingham Health Profile (NHP-PM), the Karnofsky Physical Status Scale (KPSS), the Overall Evaluation of Health (OEH), and the Somatic Symptoms Subscale from the General Health Questionnaire (GHQ-SS)

	NHP-PM	KPSS	OEH	GHQ-SS
GARS	.78	.68	−.40	.25
ADL	.77	.64	−.39	.26
IADL	.71	.66	−.37	.21

Note. GARS = Groningen Activity Restriction Scale; ADL = activities of daily living; IADL = instrumental activities of daily living.

TABLE 3—Mokken Scale Analysis for Polychotomous Items on the Groningen Activity Restriction Scale (GARS), for the Combined European Data Set (n = 623)

Ordered GARS Items		Item Mean Scores	Scalability Coefficient for the Individual Items (H_i)
1. Wash face/hands	(ADL)	1.22	.49
2. Feed yourself	(ADL)	1.24	.40
3. Get around inside house	(ADL)	1.26	.50
4. Get on/off toilet	(ADL)	1.32	.48
5. Prepare breakfast/lunch	(IADL)	1.35	.47
6. Get in/out of bed	(ADL)	1.43	.47
7. Stand up from chair	(ADL)	1.45	.49
8. Do light cleaning	(IADL)	1.54	.46
9. Dress yourself	(ADL)	1.59	.53
10. Walk outdoors	(ADL)	1.60	.50
11. Wash/dry body	(ADL)	1.76	.51
12. Prepare dinner	(IADL)	1.79	.47
13. Go up/down stairs	(ADL)	1.81	.48
14. Wash/iron clothes	(IADL)	2.07	.47
15. Take care of feet/toenails	(ADL)	2.10	.42
16. Make beds	(IADL)	2.35	.47
17. Do shopping	(IADL)	2.49	.43
18. Do heavy cleaning	(IADL)	2.79	.49
Scalability coefficient *H* of the GARS			.47
Reliability coefficient rho			.94
Scalability coefficient *H* of the ADL items			.52
Reliability coefficient rho			.90
Scalability coefficient *H* of the IADL items			.51
Reliability coefficient rho			.89

what between countries. These differences may be due to environmental and cultural differences in the appraisal of activities included in the GARS. Probably because of sex role–specific socialization patterns, women scored significantly higher than men on the IADL scale, although the mean difference was very small (means = 14.8 and 13.6, respectively). On average, older people scored significantly higher on the GARS as a whole and on the ADL and IADL scales; these higher scores support the fact that, in general, older people are more disabled than younger ones[3] (range = 32.5–27.6, 17.5–14.8, and 15.0–12.8, respectively). There were no interaction effects between age, sex, and country.

The validity of the GARS and the ADL and IADL scales was explored by assessing the scale's association with several other instruments measuring physical problems and subjective health. Specifically, we used the Physical Mobility subscale from the Nottingham Health Profile,[18,19] the Karnofsky Performance Status Scale,[20] the Somatic Symptoms subscale from the General Health Questionnaire,[21] and an overall evaluation of health item using a ruler as a visual analogue scale. In the latter case, the patient was asked, "How would you rate your health at the moment? Would you say that it is very poor, that it is excellent, or that it is somewhere in between?"[22] The ruler ran from "very poor" (a score of 1) to "excellent" (a score of 100).

The GARS and the ADL and IADL scales were expected to correlate highest with those measures most comparable to the GARS (the Physical Mobility subscale from the Nottingham Health Profile and the Karnofsky Performance Status Scale) and to correlate lowest with those instruments less comparable to the GARS (the overall evaluation of health item and the Somatic Symptoms subscale from the General Health Questionnaire) (Table 2).

The pattern of correlations encountered yielded additional support for the utility of the GARS. Moreover, from the pattern and size of the correlation coefficients, it appears that there was no difference between the GARS and the ADL and IADL scales, which may be an additional reason to treat the ADL and IADL scales as one scale. (It also appears legitimate to use the ADL and IADL scales separately if necessary.)

Results of MSP

Finally, the hierarchical ordering of the items (in the data sets of the four European countries together) was tested with MSP (Table 3). The items are ordered according to their difficulty, as expressed by the item mean scores. All the H_i's were greater than or equal to .40; the reliability coefficient rho was .94. The H coefficient of .47 nearly met the criterion for a strong scale.

Conclusions

The results of the analyses were highly satisfactory. They showed a strong and reliable general first factor, indicating one underlying dimension of disability for ADL, IADL, or both. For institutional reasons, or to differentiate between sex or age groups, the ADL and IADL scales can be used separately.

The GARS turned out to be a rather strong unidimensional, hierarchical scale. The same was even more true for the separate ADL and IADL scales. The fact that the GARS items were hierarchically ordered means that respondents with the same score had the same problems with ADL and IADL. However, Kempen et al. warn against the use of cutpoints or single

questions to categorize patients: "Hierarchical evidence should not be used to justify minimal patient questioning."[23] This has partly to do with the fact that the Mokken model is not sample independent. Differences between samples may be due to language, education, motivation, opportunity, or environmental factors (living arrangements, availability and proximity of services, means of transportation, and so on).[10,13,23–25] However, when the Mokken analysis is applied to a maximally large group, its sample dependence gradually diminishes.

One of the advantages of MSP over the Guttman analysis is that more than two response categories can be used. As a consequence, more accurate distinctions can be made, which are not only more realistic about the daily functioning of patients but also necessary to target support services.[6,8,13,23]

Of course, other instruments have been developed to measure disability in ADL or IADL,[26,27] but the GARS measures both simultaneously, and it is a very reliable and valid scale with hierarchically ordered, polychotomous items. In addition, it is community based and not disease-specific. These characteristics make the GARS very useful for comparative and longitudinal research both across countries and across diseases. □

Functional Transitions among the Elderly: Patterns, Predictors, and Related Hospital Use

Vincent Mor, PhD, Victoria Wilcox, PhD, William Rakowski, PhD, and Jeffrey Hiris, BA

ABSTRACT

Objectives. This paper describes 6-year rates and correlates of functional change in the elderly, as well as associated hospital use.

Methods. The Longitudinal Study on Aging (n = 7527) and matched Medicare claims were used to calculate 6-year functional status transition rates and hospital use rates. A hierarchical measure that incorporated activities of daily living, instrumental activities of daily living, and competing risks of institutionalization and death was used to assess functional status. Multinomial logistic regression was used to predict 1990 status.

Results. The functional status of 12% of men and women 70 to 79 years of age who were initially impaired in instrumental activities of daily living improved, and about half of the initially independent people in that age group remained so. Multivariate analyses revealed that age, baseline functioning, self-rated health, and comorbidity predicted 1990 status. Both baseline functioning and functional change were related to hospitalization.

Conclusions. This study supports others that have shown some long-term functional improvement, but more commonly decline, in the elderly. Furthermore, it documents the link between functional decline and increased hospital use. (*Am J Public Health.* 1994;84:1274–1280)

Introduction

The ability to perform routine daily tasks is an important aspect of quality of life. In general, this ability declines with age.[1,2] In 1985, an estimated 5 million community-dwelling elderly people experienced a functional impairment lasting 90 days or longer; an additional 1.3 million were institutionalized.[3] Physically disabled elderly people face an elevated risk of institutionalization and death.[4]

Disability in the elderly is not always permanent; some experience a return of lost functional capacity.[2,5–8] One purpose of this study was to examine change in functional status in Longitudinal Study on Aging participants. Although several previous studies have examined disability transitions using Longitudinal Study on Aging data,[4,6,9–13] they have used shorter time periods, been confined to subpopulations, examined a limited definition of functioning, or ignored the competing risks of death or institutionalization.

A second purpose of this study was to identify predictors of functional change in the elderly, focusing on age, gender, and self-reported health. Some evidence suggests that age decreases the likelihood of regaining lost functional ability.[2] Most, but not all, of the available data indicate a higher prevalence of disability among women than men,[1–3,14] although research concerning gender differences in the incidence of disability is inconclusive.[2,8,10,15] Positive health perceptions have been associated with a lowered risk of institutionalization, mortality, and functional decline,[7,15–18] and these associations are independent of more objective health indicators.

Little is known about the relationship between functional change and hospital use. Disability levels are positively associated with number of physician visits, length of hospital stay, use of home health services, and likelihood of both hospitalization and institutionalization.[12,19–23] However, it is not clear whether use is a function of disability per se or the process of functional decline. Thus, our third purpose was to assess the relationship between functional change and hospital use and costs.

Methods

Sample

This paper is based on (1) the Longitudinal Study on Aging person-level interview files, (2) Medicare claims files, and (3) a match of Medicare hospital claims with the National Death Index. The Longitudinal Study on Aging uses baseline data from the 1984 National Health Interview Survey (NHIS) Supplement on Aging, which involved the collection of health and social data on NHIS participants 55 years of age and older. The Longitudinal Study on Aging includes 7527 Supplement on Aging participants 70 years old or older who were still living in their respective communities in 1984. These participants were reinterviewed in 1986, 1988, and 1990. A complete description of the Longitudinal Study of Aging has been published previously.[24,25]

SUDAAN Version 6.0[26] was used in weighting and adjusting the sample for

the complex sampling design. All analyses, except where otherwise noted, involved the weighted and adjusted sample.

Measures

Health. Comorbid conditions were assessed by counting the number of serious medical problems reported by the respondent from a list of 13 conditions (e.g., stroke, broken hip, cancer). Self-rated health was assessed by the following standard NHIS question: "Would you say your health in general is excellent, very good, good, fair, or poor?" Response categories were recoded as excellent/very good, good, and fair/poor/don't know (there were some 40 "don't know" cases). "Don't know" responses were included in the latter category because previous research[27] has shown that such responses are associated with an elevated mortality risk comparable to that associated with fair self-rated health.

Functional status. Activities of daily living and instrumental activities of daily living items were used in assessing functional status. Item selection was based on preliminary analyses designed to identify the items that best predicted functional decline and mortality.[10,17] The activities of daily living items assessed respondents' ability to toilet, dress, bathe, transfer, eat, and walk. The instrumental activities of daily living items measured the ability of respondents to prepare meals, shop for personal items, and do light housework. Respondents were asked whether they had difficulty performing each activity, how much difficulty they had, and whether they received help from another person. Respondents who were "unable" or "receiving help" were classified as unable and compared with those who reported being able to perform each activity independently.

Correlations between activities of daily living and instrumental activities of daily living items are high enough to suggest that they measure a single domain, with impairment in activities of daily living more severe than impairment in instrumental activities of daily living.[22] Therefore, we constructed a hierarchical scale in which individuals were classified as (1) independent (able in all activities), (2) impaired in instrumental activities of daily living only (unable in one or more such activities), (3) moderately impaired in activities of daily living (unable in one to two such activities, irrespective of ability in instrumental activities of daily living), or (4) severely impaired in activities of daily living (unable in three or more such activities, irrespective of ability in instrumental activities of daily living). As a result of missing 1984 functional status data, 120 cases were dropped from all analyses. Several categories were added to the 1990 status outcome: institutionalized at the time of the 1990 reinterview attempt, dead, and missing. The dependent variable included a "missing" category to control for the known bias that nonresponse is correlated with disability.[28]

TABLE 1—Characteristics of Study Participants at 1984 Baseline

	Functional Status Data Available (n = 7407), %	Use Data Missing (n = 1406), %	Use Data Available (n = 6001), %	P[a]

Severely ADL disabled	4.6	8.5	3.6	

Note. IADL = instrumental activities of daily living; ADL = activities of daily living; NS = not significant.
[a]Use data available vs use data missing.

Institutionalization. To ascertain institutionalization at the time of the interview, we used the National Center for Health Statistics code indicating that subjects were not asked about receiving help with activities of daily living or instrumental activities of daily living because they resided in a nursing home. After those with missing 1984 functional status were eliminated, 262 people were residing in a nursing home at the 1990 interview.

Mortality. Mortality was based on National Death Index matching, verified by information obtained from attempts to conduct the next scheduled interview. When the National Death Index indicated that the respondent was deceased but respondent tracking information indicated that he or she was still alive, we assumed that the interview data were correct.

Hospital use. Medicare Part A and MEDPAR summary data were linked by year to Longitudinal Study on Aging participants who provided their health insurance claim number. We used the hospital claims data to determine the probability of hospitalization in each year and the associated Medicare reimbursement (standardized to 1990 dollars using the Medical Care Consumer Price Index). Respondents who were not matched on both Medicare A and B (n = 2045) or had no record of any Medicare A or B (n = 595) claims filed between 1984 and either 1990 or their death were dropped from the use analyses to avoid artificially deflating the numerator.

Note. IADL = instrumental activities of daily living; ADL = activities of daily living.

Analytic Approach

SUDAAN[26] was used to generate 6-year functional transition tables, stratified by age and sex, from the weighted data. The BMDP[29] multinomial logistic regression procedure was used in weighting the data; however, this procedure did not adjust for the complex sampling as a result of software limitations. The seven-category 1990 status variable was the outcome measure, and 1984 functioning, age, sex, self-reported health, number of serious illnesses, and an Age × Sex interaction were entered as predictors. Hospital use and reimbursements per user were calculated for 4 calendar years—1986, 1987, 1988, and 1989—and are presented here in a weighted format. The tables include actual sample size numbers, but the percentages reflect weighting.

Analyses of functional transitions were based on 7407 individuals with 1984 functional status data. Analyses of hospital use were based on a subsample of 6001 individuals for whom it was possible to match the Medicare health insurance claim number with the Longitudinal Study of Aging personal-level interview file and who had some indication of Part A or MEDPAR use for the 6-year period.

Results

Sample Characteristics

Individuals with valid 1984 functional status data were compared with the 120 individuals with missing 1984 functional status data on the sociodemographic variables, living arrangements, and self-rated health. Those with missing 1984 data had poorer self-rated health but did not differ otherwise from those with valid data.

Table 1 presents descriptive data for three groups at baseline: (1) those with valid 1984 functional status data, (2) those excluded because they could not be matched with Medicare claims data, and (3) those with valid Medicare use and 1984 functional status data. Transitions analyses were based on group 1; use analyses were based on group 3 only. The sample was predominantly female, 70 to 79 years of age, White, currently or previously married, and living with others. All groups reported a mean of six serious medical conditions.

The last two columns of Table 1 summarize chi-square tests comparing the baseline characteristics of those with valid and those with missing use data. Use data were more likely to be missing for those

Note. The reference group consists of those subjects who were independent in both activities of daily living (ADLs) and instrumental activities of daily living (IADLs) in 1990. OR = odds ratio; CI = confidence interval.

who were female, older, not currently married, and living alone and for those who had poorer self-rated health.

Functional Status Transitions

Tables 2 and 3 present transitional probabilities for functional status over a 6-year interval, stratified by age, for men and women, respectively. Over the 6-year period, stability was not the rule, except for the younger respondents who were independent in 1984. Although functional decline was more common than improvement, approximately 4% of men and 2% of women with known 1990 status improved over the 6-year interval. Most strikingly, 3.5% of the women and 7% of the men 70 to 79 years of age returned to complete independence after being in the most severely impaired condition in 1984.

Despite improvement in a minority of the functionally impaired at baseline, most had died by 1990. Among the survivors, disability increased the likelihood of being in an institution in 1990; nonetheless, the majority of elderly respondents impaired in activities of daily living were residing in the community at the follow-up interview. Men were more likely to die than women, and women were more likely to be institutionalized.

Predictors of Functional Transitions

Table 4 shows the results of the multinomial logistic regression predicting 1990 outcomes while adjusting for age, gender, self-rated health, number of medical conditions, baseline functional status, and the interaction between age and gender. Odds ratios and associated 95% confidence intervals are presented for five outcome states; independence in 1990 is the reference outcome. Although results for those with missing 1990 outcome data are not shown, the model adjusts for this competing risk. The odds ratios for each outcome adjust for the competing risks of being in a different outcome state and are expressed relative to being in the independent category. Because 1984 functional status is entered into the equation, the analysis predicts change from 1984 to 1990.

Functional impairment in 1984 was strongly related to functional independence in 1990, to being in a nursing home, and to having died. Being 80 years of age or older was associated with at least a two-fold risk of being in a nonindependent state in 1990 and more than a fourfold increased risk of death. Gender had a small but statistically significant effect on being moderately disabled but had no effect on the other disability states. While women were much less likely to have died, controlling for other factors, we found no significant effect of gender on being in a nursing home. Health status, measured both as the number of serious comorbidities and as self-rated health, was related to all outcomes.

Functional Transitions, Hospital Use, and Cost

Table 5 shows Medicare-reimbursed hospital use and 1990 costs in relation to functional status transitions. The two groups that were impaired in activities of daily living were combined in these analyses. For each group defined by 1984 and 1990 functional status, Table 5 shows use during 1986, 1987, 1988, and 1989. To illustrate, for elderly people who remained independent from 1984 to 1990, an estimated 13% had at least one hospital visit in 1986, at a mean cost per user of $8957. In 1987, 14% of this group were hospitalized, at a mean cost of $9085 per user.

Several points in Table 5 are noteworthy. First, functional decline was associated with higher hospital use rates. For example, 20% of initially independent persons who were dependent in activities of daily living in 1990 were hospitalized in 1986 (vs 13% among those who remained independent); by 1989, 31% had been hospitalized. Second, those who improved had lower rates of hospitalization than those who remained dependent, particularly as 1990 approached. Indeed, the minority who returned to independence had 1989 hospitalization rates similar to initially independent respondents. Third, proximity to death tended to be associated with an increased probability of hospitalization and higher costs per user.

Discussion

Our results support previous research showing considerable changes in functional status in the elderly. The probability of functional improvement was similar to that found in a recent study.[28] Return to independent functioning following even severe disability did occur. However, stability and improvement were rare among those 80 years old and older; age clearly influences the course of disability and the likelihood of death, even for elderly people with similar baseline functioning.

The fact that a higher percentage of women than men experienced functional decline and institutionalization appears to

Note. The denominator is the number of individuals alive and in that status in 1984 and 1990. IADL = instrumental activities of daily living; ADL = activities of daily living.

reflect women's greater likelihood of survival. This conclusion is supported by previous reports that women who become disabled live longer than their male counterparts[3,12,30] but are more likely to enter a nursing home.[4] Our analyses highlight the importance of controlling for the competing risks of dying and institutionalization when investigating the possibility of gender differences in functional change. After adjusting for initial disability and competing risks, we found no consistent effects of gender on changes in physical functioning, corroborating recent reports.[2,7]

Our study extends the literature demonstrating the ability of personal health appraisals to predict future health outcomes by showing that self-rated health predicts subsequent functional status, institutionalization, and death, even when these competing risks are included in a single model. Elderly people who rated their health as less than excellent were more likely to be disabled, institutionalized, or dead in 1990, even after controlling for 1984 functional status and the presence of serious disease.

This study assessed the point prevalence of institutional residence in 1990 rather than the cumulative prevalence of nursing home placement during the 6-year interval. Because nursing home episodes that ended before 1990 were not included in our measure, our results underestimate the 6-year incidence of nursing home placement. Many individuals have relatively short nursing home episodes before returning home or dying.[31–33]

To our knowledge, this is the first study to examine hospital use in association with functional status transitions. Elderly respondents who were more disabled at baseline showed higher use rates and costs during each time interval examined. The costs per user increased over time for each group defined by initial functional status. This pattern of increasing costs was most notable among those who died. These findings are consistent with a report from Health Care Financing Administration analysts who examined Medicare payments for cohorts over 16 years.[34]

Individuals whose functional status improved showed a reduced likelihood of hospitalization in future years. This suggests that temporary impairment is associated with a transient elevation in health care costs that presumably dissipates once the medical cause of the impairment has resolved. Among elderly respondents whose status declined, use increased for those who had no impairment at baseline but not for those with preexisting impairment in 1984. Thus, it appears that the emergence of new disability in previously independent elderly people, rather than the exacerbation of impairment in those previously disabled, leads to an increase in use. However, the temporal sequencing of our data dictates that any conclusions about causal relationships be viewed as tentative.

Our study is limited by the fact that we did not consider intermittent transitions during the 6-year period. However, the consistent level of fluctuation observed in both 2- and 4-year periods across multiple data sets suggests that there are probably real transitions in health and functioning as well as more transitory fluctuations that are at least partially due to acute states that affect functioning.[16,28] Future research should examine the periodicity of these fluctuations to improve current transition rate models.

Another limitation is the high and biased rate of failure to match claims data. Those without matched Medicare data were older, in poorer self-rated health, and more likely to be female. These factors are associated with greater use[35]; thus, our analyses probably underestimate use. In contrast, our decision to exclude matched cases without any claims may have biased toward overuse, but analyses comparing claims and self-reported hospitalizations in these data suggest that the claims may be incomplete, thus justifying our decision.[36] Future studies should use more complete measures of use. Furthermore, since functional status is largely the outcome of multiple disease and age-related processes, our analyses cannot address the "true" causes of hospitalization.

In summary, our analyses indicate some long-term functional improvement, even among those in their 70s. However, decline and death were more prevalent, particularly in men 80 years of age and older and among the elderly with a preexisting disability. Illness and perceived health are robust predictors of all future outcome states, even more so than age and nearly as much as function. Finally, as has been long suspected, functional change is strongly related to future hospital use, with decreased use associated with improvement and increased use associated with decline, particularly as death approaches. □

New Toll-Free Hotline of Resources on Domestic Violence

With domestic violence at epidemic proportions in the United States, the Family Violence Prevention Fund has established a hotline to provide health professionals with resources to better understand and treat victims of spouse abuse. By calling the Health Resource Center On Domestic Violence at 1-800-313-1310, health professionals can request data and materials designed specifically for their specialty, technical assistance for developing domestic violence programs and protocols, and advice from specialists. Health researchers, journalists, and local, state, and federal policymakers also can request information and assistance through the hotline, which is funded by a grant from the US Department of Health and Human Services.

The hotline operates weekdays from 9 AM to 5 PM Pacific time. Callers can request the following:

- Resource materials, including general information on strengthening health care providers' response to domestic violence, and materials specifically designed for a variety of health care specialties
- Technical assistance, including help developing hospital- or clinic-based domestic violence programs and protocols
- Library services, including advice from information specialists who can provide customized computer literature searches, research studies, and other published materials from the nation's most extensive domestic violence collection

A collaborative effort between the Family Violence Prevention Fund and the Trauma Foundation, this special service library maintains a collection of journal articles, reports, surveys, government documents, curricula, and protocols on domestic violence. Library staff have access to MEDLINE and numerous other computer databases, electronic mail, and the Internet. The library is located at the Pacific Center for Violence Prevention at San Francisco General Hospital. In order to cover costs, the library will charge a photocopying fee and postage for materials provided.

The hotline is one of a series of Family Violence Prevention Fund activities. Later this year, the fund will release the results of a national survey assessing whether nurse managers and physician directors at hospital emergency departments around the country are trained to identify and treat victims of domestic violence. With support from the Advertising Council, the fund will also launch a national public education campaign to promote the prevention of domestic violence.

The Outcomes of Patients Newly Admitted to Nursing Homes after Hip Fracture

ABSTRACT

Objectives. The outcomes of elderly, hospitalized patients discharged to nursing homes after hip fracture were examined.

Methods. For 2624 hip fracture patients admitted to any of 43 proprietary nursing homes between 1984 and 1988, admission assessments were examined in relation to 1-month outcomes.

Results. Mean patient age was 82 ± 7 y; 85% of the sample were female. Within 1 month after discharge, 24% had returned home, 12% had been rehospitalized, 3% had died, and 61% remained in the nursing home. Characteristics significantly associated with mortality included disorientation, functional dependency, neurologic diagnoses, and use of cardiac medications, antidepressants, or narcotics. Rehospitalization was significantly associated with age, gender, living with someone, being ambulatory, and functional dependency. Returning home was associated with younger age, living with someone, being ambulatory, and having no disorientation, functional dependency, or psychiatric or neurologic diagnoses, nor any pressure sores.

Conclusions. Better-functioning persons and those with social support returned home; physically and cognitively impaired persons and those taking narcotics, cardiac medications, or antidepressants were likely to die; and younger men, those with social support, those with functional dependency, and those who were free of disorientation were more likely to be rehospitalized. (*Am J Public Health.* 1994;84:1281–1286)

Introduction

Since the advent of prospective payment to hospitals, the recuperative phase of treatment for acute conditions such as hip fracture has shifted to the nursing home. Hospital length of stay for hip fracture patients has decreased by 4 to 9 days,[1–4] the number of in-hospital physical therapy sessions has decreased by as much as 50%,[1–3] the number of patients discharged to nursing homes has more than doubled,[2] and the percentage of patients still in nursing homes 6 months after hospital discharge has increased from 13% to 39%.[2] This shifting of the rehabilitative burden from the acute care hospital to the nursing home makes it particularly important for skilled nursing homes to identify patient characteristics associated with either successful rehabilitation or deterioration.

Two recent but small (n's = 114 and 151) prospective studies have examined patient- and setting-specific characteristics associated with returning home vs staying in the nursing home.[5,6] To expand upon these studies, we examined determinants of all potential outcomes (returning home, returning to hospital, dying, or remaining in the nursing home) in patients newly admitted to skilled nursing homes following hip fracture. We hypothesized that individuals with more comorbidity, those who were more functionally dependent, disoriented, immobile, and taking more drugs, would be less likely to return home and more likely to return to the hospital or to die.

Methods

Study Population

Data used in this study come from regular assessments of residents in 43 continuously owned facilities of the National Health Corporation located in Missouri (n = 9), Kentucky (n = 4), South Carolina (n = 5), and Tennessee (n = 25). The sample comprised all residents 65 years of age and older whose primary insurer was Medicare and who had been newly admitted to one of the nursing homes from a hospital between 1984 and 1988 with a primary *International Classification of Diseases,* Ninth Revision, Clinical Modification[7] (ICD-9-CM) diagnosis of hip fracture (ICD-9-CM codes 820.00, 820.02, 820.03, 820.09, 820.20, 820.21, 820.22, and 820.8). These new admissions had never been residents of a National Health Corporation facility, but 38.3% had been institutionalized elsewhere before their hip fractures. The National Health Corporation maintains a comprehensive computerized clinical database of resident characteristics. Data are collected in monthly assessments of all Medicare-covered residents by trained nurses, submitted to a central office for computerization, and reviewed for completeness by corporate staff. Assessments are used within each facility to monitor resident status and to allocate staffing

[b]Diagnostic categories were created by grouping ICD-9-cm diagnoses listed as secondary diagnoses.

resources. Priority is given to obtaining high-quality data, and a 10% sample is audited quarterly by a second specially trained nurse. The average percentage disagreement across all homes between the two nurse assessors was 9% for the subset of variables examined quarterly for reliability (mobility, activities of daily living, continence, pressure ulcers, selected ICD-9 codes, orientation, and behavior) (phone communication, Julia Powell, RN, Vice President of Patient Services, National Health Corporation).

Many National Health Corporation homes admit hospital patients for rehabilitation following an acute illness such as a hip fracture or stroke. Accordingly, these facilities have a higher percentage of residents covered by Medicare (57.2%) than the national average of 11.5% of hip fracture admissions.[8]

Definition of Variables

Variables for this study were derived from resident assessments performed within 7 days of admission to the homes. Independent variables fell into three broad categories: sociodemographic, functional, and medical severity. On the basis of previous literature, variables were chosen from the complete database that might, a priori, be associated with early (within 1 month) transitions from the nursing home. When two variables captured similar information (e.g. "cardiac diagnoses" and "cardiac medications"), we chose one of them. Sociodemographic variables included age, sex, and living situation prior to fracture (alone vs with another person). Functional variables included ability to walk alone or with help (yes/no), orientation (disoriented/occasionally disoriented/clear), and dependency in activities of daily living (bathing, dressing, toileting, transferring, eating). To account for medical disease severity, we postulated a priori that certain categories of secondary diagnoses might influence short-term outcomes in hip fracture patients newly admitted to nursing homes. ICD-9-CM diagnoses were grouped into four such categories: psychiatric diagnoses, cardiac diagnoses, infectious disease diagnoses, and neurological diagnoses. For example, psychiatric diagnoses present in the study population included "organic psychosis," "schizophrenia," "psychosis," "paranoia," "organic brain damage," and "other mental disorders." We also examined commonly used medications such as cardiac medications, antidepressants, and narcotics. Finally, we categorized patients as to whether or not they had pressure ulcers at admission.

For each subject, outcome status (returned home, remained in nursing home, returned to hospital, died) was examined at 1 month. Since our interest was in identifying characteristics associated with the first transition within 30 days of admission, we did not track subjects past the first transition. Thus a person discharged to a hospital and dying in the hospital within 30 days of nursing home admission would be categorized as a discharge to hospital.

Statistical Analysis

Bivariate associations between independent variables and the four possible outcomes were examined by means of chi-square tests of association. All bivariate associations between independent variables and the four possible outcomes that were significant ($P \leq .10$) were fitted to a polychotomous logistic regression model, a generalization of logistic regression to more than two outcome categories (e.g., home, nursing home, hospital, death). Collapsing any of the four outcome states would obscure important relationships. A polychotomous model assumes that the possible outcomes compete with each other and are mutually exclusive. The parameters of the model were estimated by maximizing a likelihood function by means of the mlogit procedure in STATA Release 3.[9] To interpret coefficients of independent variables in a polychotomous model, one of the outcomes is assigned as a referent category; for this analysis, the referent category was remaining in the nursing home. The adjusted relative risk of an outcome of interest for a given independent variable represents the risk (adjusted for other variables in the model) of experiencing that outcome instead of the referent outcome, given the competing risks of experiencing other possible outcomes. This analysis was repeated after stratifying by living arrangement prior to hip fracture (institutionalized vs noninstitutionalized), since these two groups would be expected to have distinctly different premorbid profiles.

Results

Sample Description

Between 1984 and 1988, 2624 Medicare patients were newly admitted to a National Health Corporation nursing home with a primary diagnosis of hip fracture. The mean age of the sample was 83 (± 7) years, 83% were female, and 38% were living in an institution at the time of their fractures (Table 1). Only 29% were able to walk alone or with assistance, but 59% of the sample were able to perform all activities of daily living. More than half of the subjects were clear in their orientation. The number of secondary diagnoses (out of a possible total of eight) was equally distributed across groupings of 0 through 2, 3 or 4, and 5 through 8. Cardiac diagnoses were listed most often as secondary diagnoses, followed by neurological, psychiatric, and infectious disease diagnoses. Approximately 20% of the sample had pressure ulcers.

Table 2 displays the 1-month transition of the original cohort of 2624 patients and the cohort stratified as to prehospital living situation. Within the first month, 23.7% had returned home, 12.4% had been sent back to an acute care hospital, 3.1% had died, and 60.8% were still in the nursing home. Previously institutionalized hip fracture patients were less likely than previously noninstitutionalized persons to return home (17% vs 28%; $P < .05$).

TABLE 2—First Transition within 30 Days of Admission of Patients Newly Admitted to Nursing Homes with Hip Fractures

Transition	All Patients (n = 2624)	Previously Institutionalized* (n = 1005)	Previously Noninstitutionalized* (n = 1619)
Home, %	23.7	16.9	27.9
Still in nursing home, %	60.8	65.8	57.7
Hospital, %	12.4	13.6	11.6
Dead, %	3.1	3.7	2.8

*$P < .0001$ for the difference in outcomes between previously institutionalized and noninstitutionalized patients.

[b]Activities of daily living (ADLs) include bathing, dressing, toileting, transferring, eating/feeding, and grooming.

Polychotomous Logistic Regression Results

We included all of the above independent variables in a polychotomous logistic regression model except cardiac diagnoses ($P = .97$, bivariate) and number of secondary diagnoses (collinear with individual diagnostic categories), since all bivariate associations were highly statistically significant (data not shown). As shown in Table 3, after all other variables in the model were controlled, older age reduced the probability of returning home or to hospital. Being female reduced the likelihood of returning to hospital and tended to lower the risk of mortality (not statistically significant at $P < .05$). Living with someone increased the probability of returning home and of being rehospitalized. Having any dependency in activities of daily living strongly increased the risks of death, rehospitalization, and not being able to return home. Disorientation was the strongest predictor of death and greatly decreased the probability of returning home. The ability to walk slightly increased the likelihood of returning home or to hospital but was not significantly associated with death. The presence of a pressure ulcer significantly reduced the probability of returning home, but was not associated with a significantly higher risk of death. When the total number of medications, as well as all other variables in the model, were controlled, the use of cardiac medications, antidepressants, and narcotics contributed independently to a higher risk of dying. Having secondary neurological diagnoses reduced the likelihood of rehospitalization, returning home, and death.

When the analysis was repeated after stratifying by living arrangement prior to hip fracture, the results were different (Tables 4 and 5). For previously noninstitutionalized persons, the model was similar to that of the overall sample, although slightly greater effect sizes were observed for the association between disorientation, cardiac medications, antidepressants, and death, whereas narcotic use

was no longer significant, probably because of a smaller sample size. For previously institutionalized persons, the association between dependency in activities of daily living and death was stronger. Disorientation did not significantly increase the risk of death; however, it reduced the probability of returning home more for the previously institutionalized than for the previously noninstitutionalized. The ability to walk, alone or with help, did not increase the likelihood of returning to the hospital, as it had for noninstitutionalized persons. The use of cardiac medications or antidepressants was not associated with mortality in the previously institutionalized group; however, the use of narcotics did increase the probability of returning home for persons in this group.

Discussion

One month after admission to a nursing home following hip fracture, 24% of elderly Medicare patients had returned home, 61% were still in the nursing home, 12% had been sent back to the hospital, and 3% had died. The mortality rate in this group was slightly less than the rates of 6% to 12% for all hip fracture patients reported by others,[10-13] but closer to the 4% annual mortality for nursing home residents reported by Keene.[10] Entry characteristics independently associated with the first transition within 30 days included age, sex, premorbid living arrangement, functional status, orientation, mobility, neurological diagnoses, and the use of cardiac medications, antidepressants, and narcotics. Results for the previously institutionalized group differed in some instances from those for the previously noninstitutionalized. The ability to walk did not increase the likelihood of returning home for the previously institutionalized, as it had for the previously noninstitutionalized, whereas narcotic analgesic use was associated with returning home only in the previously institutionalized. The hypothesis that risk factors associated with different outcomes would overlap was only partially supported by our findings. With the exception of disorientation and dependency in activities of daily living, admission characteristics differed in their association with the four outcomes.

An important feature of our study is the focus on simultaneously considered outcomes in a large sample of residents from multiple nursing homes. Previous studies of hip fracture patients treated in nursing homes involved relatively small numbers of residents in a limited number of facilities, and the studies focused only on patients' returning home. Our data clearly reveal that this simplification is gained at the expense of precision. Had we focused only on patients' returning home, the contrast between remaining in the nursing home and dying or being rehospitalized would have been lost. Furthermore, combining these outcomes would yield an incorrect estimate of the effect of each independent variable. Consequently, all estimates of the effect of functioning or medical morbidity on given outcomes must be conditioned upon consideration of all the mutually exclusive outcomes.

Previous studies have demonstrated a strong relationship between dependency in activities of daily living and mortality among community-dwelling elders[15] and among persons discharged from nursing homes,[16,17] but to our knowledge this is the first study to describe, by means of multivariate models, the association between functional status and mortality during the first 30 days of nursing home residence. Our finding that functional dependency decreases the probability of returning home has also been reported by others.[5,10] Although we considered functional status at time of admission to the nursing home, rather than prior to fracture, our results were consistent with those of Keene and Anderson.[10] The finding that functional status and the ability to walk had a modest positive effect on rehospitalization as well as on the probability of returning home may imply that these factors not only reflect successful rehabilitation, but also influence the decision to rehospitalize a patient who has an acute decline during rehabilitation.

Disorientation at admission was one of the strongest predictors of mortality, even after other baseline characteristics were controlled. Delirium probably accounts for a significant percentage of residents in this category, since previous work has shown that up to 37% of patients developing delirium in the hospital still have this diagnosis at discharge.[18] The observation that delirium is an important predictor of mortality[12,19,20] may partly reflect the fact that delirium is associated with the presence of significant underlying medical problems. Indeed, an independent effect of delirium on mortality could not be demonstrated in two recent studies that also controlled for illness severity.[18,21] Our finding of an independent effect of

disorientation after controlling for comorbidities and functional status may reflect the medical vulnerability of this condition.

In this study, several diagnoses and medications were associated with 1-month outcomes, possibly serving as comorbidity measures or disease severity measures. For example, neurological secondary diagnoses decreased the probability of all outcomes, and cardiac medications increased both mortality and the likelihood of returning to the hospital. Similarly, the finding that pressure ulcers were associated with a decreased probability of returning home and a trend toward an increase in mortality might be interpreted as simply a reflection of pressure ulcers as markers of underlying medical problems and poor mobility[22]; however, these associations remained after we controlled for functional status, ability to walk, and secondary diagnoses, suggesting an independent effect. Finally, the finding that antidepressant use increased the risk of death more than three times may have arisen because of adverse events associated with the use of antidepressants, such as falls, hip fracture, and cardiac conduction abnormalities,[23] or because the prescribing of these drugs may be selective for those individuals with underlying conditions that are themselves associated with greater mortality. This link would also be a plausible explanation for the strong association between cardiac medication use, narcotic drug use, and mortality.

The unexpected finding that women were less likely than men to be rehospitalized is the first demonstration of an association between sex and hospitalization rates among nursing home residents. The finding that persons with hip fracture who were living with someone prior to fracture were more likely to return home and more likely to be rehospitalized probably reflects the importance of caregiver support at home as well as caregiver advocacy when clinical deterioration occurs.

Our results must be interpreted with consideration of several features. First, this was not a random sample of patients admitted to nursing homes with hip fracture. Second, some of the assessments may be imprecise; however, since the data are collected uniformly and used routinely by the National Health Corporation to assess staffing needs and to improve the efficiency of patient care, these assessments are carefully monitored for accuracy. Since the variables are carefully defined in a coding manual, and since the reliability was high, the chance of misclassification was small. Reviewers were always charge-level nurses on the units who were not motivated by corporate incentives such as reimbursement.

Neurological diagnoses	0.64	0.47, 0.87	0.66	0.44, 0.98	0.25	0.10, 0.62

Note. OR = adjusted odds ratio for 1-month outcome; CI = confidence interval.
[a]"Staying in nursing home" was the referent outcome.
[b]Activities of daily living (ADLs) include bathing, dressing, toileting, transferring, eating/feeding, and grooming.

Despite these limitations, the findings from this study extend the work of previous studies and capitalize on the large database of the National Health Corporation. Furthermore, our findings are more precise because we considered all outcomes simultaneously. Simplifying the analysis by combining outcomes could lead to a misinterpretation of effects. This method of modeling outcomes would be directly applicable to other conditions requiring rehabilitation in the nursing home, such as stroke. Future studies of such conditions may be able to distinguish patient characteristics that are either generic to rehabilitation in the elderly or disease-specific. □

Treatment and Survival among Elderly Americans with Hip Fractures: A Population-Based Study

ABSTRACT

Objectives. This study was undertaken to examine the patterns of treatment and survival among elderly Americans with hip fracture.

Methods. A 5% national sample of Medicare claims was used to identify patients who sustained hip fractures between 1986 and 1989. In comparing treatment patterns across regions, direct standardization was used to derive age- and race-adjusted percentages. Logistic regression and Cox regression were used to examine short- and long-term survival.

Results. In the United States, 64% of femoral neck fractures were treated with arthroplasty; 90% of pertrochanteric fractures were treated with internal fixation. Higher short- and long-term mortality was associated with being male, being older, residing in a nursing home prior to fracture, having a higher comorbidity score, and having a pertrochanteric fracture. Blacks and Whites had similar 90-day postfracture mortality, but Blacks had a higher mortality later on. For femoral neck fracture, internal fixation has a modestly lower short-term mortality associated with it than arthroplasty has.

Conclusion. Variation in the treatment of hip fracture was modest. The increased delayed mortality after hip fracture among Blacks requires further study. (*Am J Public Health.* 1994;84:1287–1291)

Introduction

More than 200 000 hip fractures occur annually in the United States,[1,2] with appreciable associated morbidity and mortality. Despite the human and economic burden of these fractures, relatively little is known about the patterns of treatment or of survival following different treatments.

Although several studies have identified factors related to postfracture survival,[3–6] their results may not be generalizable for several reasons. For example, patient characteristics and surgical practice may vary from one institution to another. The limitations of sample size, the difficulties in comparing crude mortality rates, and the differences in the criteria used to determine treatments further hamper interpretation. To overcome these limitations, we used a 5% sample of national Medicare claims to examine the patterns of treatment for hip fracture and of survival following the most commonly used procedures.

Methods

Identification of Cases

The 5% national Medicare claims database was searched for evidence of hip fracture during the years 1986 to 1989. Both hospital (Part A) and physician (Part B) claims were used. A patient was identified as having an acute hip fracture if he or she had a discharge diagnosis of hip fracture (*International Classification of Diseases,* 9th edition [ICD-9] codes 820.0 to 820.9) or if there was a physician claim indicating a treatment for hip fracture (current procedure terminology [CPT] codes in the range 27230 to 27248). A detailed algorithm for case identification has been described elsewhere[7] and can be obtained from the authors. Patients were excluded from analysis if there was evidence of bone or metastatic cancer, fractures of the femoral shaft or pelvis, or surgery for previous hip fracture. In addition, patients were excluded if they were under age 65, not resident in the United States, or likely to have incomplete claims data because they were not enrolled in both Medicare Parts A and B, were enrolled in a health maintenance organization (HMO), or were receiving coverage through railroad board entitlement.

Definitions of Variables

The site of fracture and treatment were determined from the ICD-9 diagnosis and procedure codes on the hospital claims and from the CPT procedure codes on the physician claims. Fractures were designated as occurring either at the femoral neck or at another site ("pertrochanteric fractures"). Patients receiving internal fixation could be uniquely identified, but since the claims coding could not reliably distinguish between unipolar hemiarthroplasty, bipolar hemiarthroplasty, and total hip replacement, these procedures were grouped together as "arthroplasty." Patients for whom neither

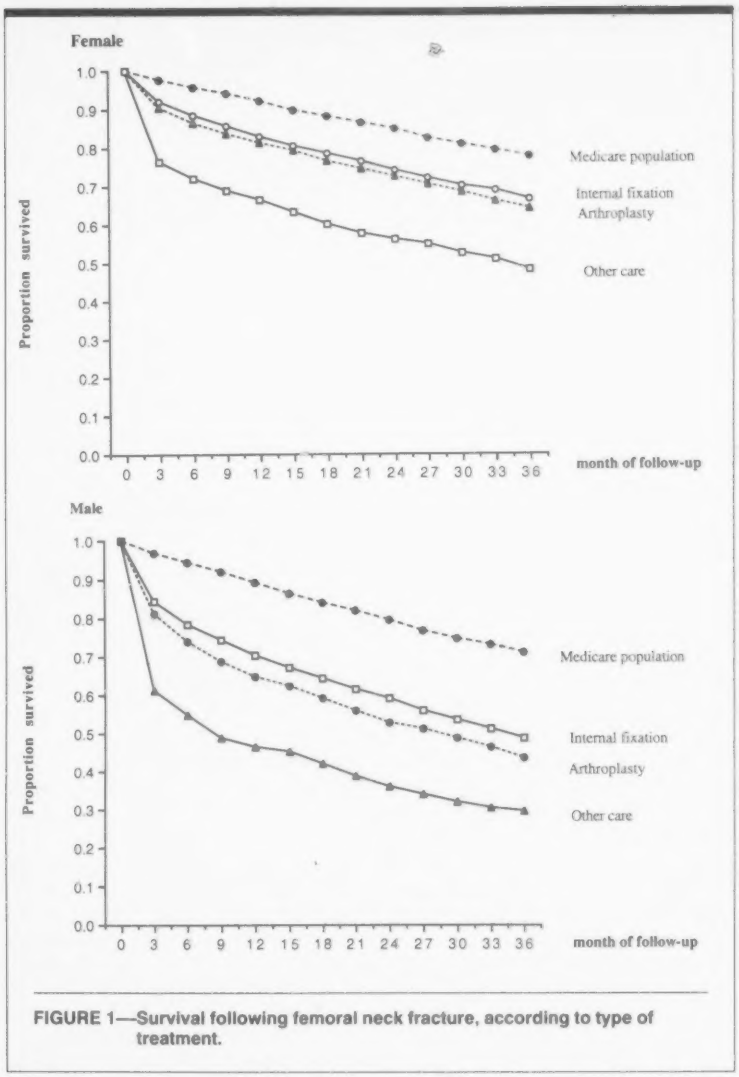

FIGURE 1—Survival following femoral neck fracture, according to type of treatment.

internal fixation nor arthroplasty were coded were considered together as a third treatment category ("other care"). Both hospital and physician claims were used to clarify ambiguity or compensate for missing data from any one source. However, because the accuracy of the hospital claims coding has been investigated and found to be excellent for hip fracture,[8] the hospital designation was used in those cases in which the hospital and physician claims disagreed.

Medicare enrollment status, date of birth, sex, race, residence, vital status as of December 31, 1990, and date of death (if any) were obtained from the Health Care Financing Administration denominator files for 1986 to 1990. A comorbidity score based on the presence or absence of a range of diagnoses recorded in the hospital claims filed for the fracture hospitalization or for hospitalizations during the 6 months prior to hip fracture was calculated using our adaptation[7] of the method described by Charlson et al.[9] A patient was identified as being a nursing home resident if his or her Part B physician claims indicated at least one physician visit occurring in a nursing home in the 3 months preceding the hip fracture. (Federal regulations for skilled and intermediate care facilities require at least this frequency of physician visits for certification.) Since only those who fractured a hip after July 1, 1986, had adequate information on comorbidity and prefracture residence, analyses were restricted to patients with hip fractures occurring between July 1, 1986, and June 30, 1989.

Statistical Analysis

In the investigation of geographic variations in treatment, age- and sex-adjusted proportions of patients receiving a given treatment were calculated for each census division and fracture type, using direct standardization with all patients of the fracture type as the standard population.[10] Logistic regression was used to examine the association between patient characteristics and treatment choice.[11] The reference group (Medicare population) shown in Figure 1 provides a representative survival experience of all those in the 5% Medicare sample at the end of 1987 (midpoint in our time period), with the same sex/race/age structure and inclusion criteria as those for the femoral neck fracture patients. The duration of survival postfracture was calculated from the date of the admission for the hip fracture to the date of death or to December 31, 1990. To distinguish early deaths that might be associated with the treatment, separate analyses were conducted for mortality within 90 days and for survival experience beyond 90 days, using logistic regression[11] and Cox proportional hazards regression,[12] respectively. For the latter, log-log plots of all variables were used to assess the proportional hazards assumptions. To examine whether the effect of treatment on survival varied with time in the Cox regressions, separate proportional hazards models were fitted for several follow-up periods, and the statistical significance of the interaction term between treatment and the logarithm of follow-up time was tested.[12] Because no evidence of time-varying effects beyond 3 months post–hip fracture was found, only the overall relative risks for the late survival analyses are presented.

Covariates included in the models were age, sex, race, prefracture residence, comorbidity, site of fracture, and treatment. To account for the effect of comorbidity, two analytical approaches were used: one included exact comorbidity score in the model, and the other used dichotomized comorbidity status (low comorbidity [Charlson score = 0] vs high comorbidity [Charlson score > 0]). Because both approaches gave very similar results, only the model with dichotomized comorbidity status is presented.

TABLE 1—Characteristics of Patients, by Site of Fracture and Treatment

	Femoral Neck Fracture (n = 13 167)			Other Hip Fracture (n = 13 267)		
	Internal Fixation (n = 3569)	Arthroplasty (n = 8458)	Other Care (n = 1140)	Internal Fixation (n = 11 935)	Arthroplasty (n = 417)	Other Care (n = 915)
Sex[a]: female, %	77.9	80.1	73.7	78.6	76.3	74.5
Race[a]						
White, %	95.1	94.6	91.8	95.3	94.2	94.1
Black, %	3.6	3.6	5.4	2.9	3.8	4.5
Age[b]: mean, y	80.2 ± 0.1	81.1 ± 0.1	81.6 ± 0.2	82.2 ± 0.1	81.8 ± 0.4	82.1 ± 0.3
Prefracture residence[a]: nursing home, %	17.3	16.1	26.0	19.6	17.0	22.1
Comorbidity[b]: mean score	0.68 ± 0.02	0.65 ± 0.01	0.77 ± 0.03	0.67 ± 0.01	0.61 ± 0.05	0.83 ± 0.04

[a]The entries in the table indicate the percentage of patients with certain characteristics among those who have the same site of fracture and treatment.
[b]The entries in the table are the mean and the standard error of the mean.

Results

Case Population

We identified 31 467 candidate hip fracture cases that occurred between July 1, 1986, and June 30, 1989. From those, we excluded 2260 patients who were under age 65, or not resident in the United States, who had evidence of cancer or previous hip surgery, or who had insufficient evidence of hip fracture. Another 2433 patients were excluded because they were not enrollees of both Medicare Parts A and B, were members of HMOs, or were railroad board enrollees. Another 340 cases had multiple hip fracture sites. The remaining 13 167 femoral neck fractures and 13 267 pertrochanteric fractures constituted the basis for this report.

The majority of patients with hip fractures were White women over age 80 (Table 1). Femoral neck fractures and pertrochanteric fractures occurred at similar frequency, but the average age at pertrochanteric fracture was slightly higher than that at femoral neck fracture. The great majority of hip fractures were treated with internal fixation or arthroplasty. Patients treated with other care were more likely to be nursing home residents and to have a higher comorbidity score (Table 1).

Factors Associated with Surgical Treatments

More than half of the femoral neck fractures were treated with arthroplasty (8458/13 167), whereas most pertrochanteric fractures were treated with internal fixation (11 935/13 267) (Table 1). Geographic variation in treatment patterns for both types of fracture was modest. The age- and sex-adjusted proportion of femoral neck fractures treated with arthroplasty ranged from 63% to 68% among the nine census divisions; the adjusted proportion of pertrochanteric fractures treated with internal fixation ranged from 88% to 92%.

Since the great majority of pertrochanteric fractures were treated with internal fixation, the association between patient characteristics and the type of treatment was examined only for femoral neck fractures. Among patients over 65, arthroplasty was more likely to be performed in women, older patients, and those persons not living in nursing homes before hip fracture (Table 2).

TABLE 2—Patient Characteristics and the Relative Likelihood of Being Treated by Arthroplasty among Those with Femoral Neck Fractures (n = 13 167): A 5% National Sample of Medicare Claims, 1986 through 1989

	Odds Ratio[a]	95% Confidence Interval
Female	1.00	. . .
Male	0.84	0.77, 0.91
Low comorbidity	1.00	. . .
High comorbidity	0.95	0.88, 1.02
Non–nursing home	1.00	. . .
Nursing home	0.79	0.72, 0.87
White	1.00	. . .
Black	0.90	0.74, 1.08
Other	1.07	0.81, 1.41
Age, y		
65–69	1.00	. . .
70–74	1.09	0.96, 1.24
75–79	1.20	1.06, 1.35
80–84	1.26	1.12, 1.42
85–89	1.23	1.10, 1.39
90+	1.17	1.03, 1.33

[a]Adjusted for age, sex, race, comorbidity, and place of residence before fracture.

Factors Associated with Mortality

Excess mortality associated with hip fractures was most pronounced in the first several months. The 30-day mortality for men and women was 11% and 6%, respectively, whereas the mortality of an age-matched Medicare population was less than 1%. Taking all patients together, the overall post–hip fracture mortality among Medicare beneficiaries was 7% at 1 month, 13% at 3 months, and 24% at 12 months.

Both short- and long-term mortality were higher among patients who were older, were male, resided in a nursing home, had significant comorbid conditions, or had pertrochanteric fracture (Table 3). After taking these factors into account, there was no significant difference in mortality between Blacks and Whites during the first 90 days postfracture. However, the subsequent mortality was higher in Blacks (rate ratio [RR] = 1.21; 95% confidence interval [CI] = 1.08, 1.36) (Table 3). This pattern was found in all census divisions except New England, which had only 12 Blacks with hip fracture during the study period.

TABLE 3—The Effects of Various Risk Factors on Mortality after Hip Fracture

Risk Factors	0–90 Days[a] Odds Ratio	0–90 Days[a] 95% Confidence Interval	91 Days–3 Years[b] Rate Ratio	91 Days–3 Years[b] 95% Confidence Interval
Site of fracture: pertrochanteric/neck fracture	1.18	1.06, 1.30	1.08	1.02, 1.15
Age: 1-year increase	1.07	1.06, 1.07	1.05	1.04, 1.05
Sex: male/female	2.21	2.04, 2.40	1.65	1.57, 1.74
Race				
Black/White	1.01	0.83, 1.23	1.21	1.08, 1.36
Others/White	0.77	0.57, 1.03	1.65	1.41, 1.94
Comorbidity[c]: high/low	1.89	1.75, 2.04	1.74	1.67, 1.82
Residence: nursing home/non–nursing home	1.39	1.28, 1.52	1.54	1.46, 1.62
Treatment (femoral neck fractures only)				
Arthroplasty/internal fixation	1.21	1.06, 1.38	1.05	0.98, 1.13
Other care/internal fixation	3.24	2.71, 3.87	1.31	1.16, 1.48

Note. For both logistic and proportional hazard models, covariates in the model were age (interval width-1 year), sex, race, comorbidity (low and high), prefracture residence, site of fracture, and treatment.
[a]Calculated using logistic regression.
[b]Calculated using Cox proportional hazard regression.
[c]Comorbidity score greater than or equal to 1 was classified as high comorbidity.

Patients with other, unknown, or missing race also had increased long-term mortality compared with Whites.

For patients with femoral neck fractures, patterns of treatment-specific mortality were examined (Table 3, Figure 1). Patients treated with other care suffered higher mortality than those treated with internal fixation or hemiarthroplasty (Figure 1). Patients treated with arthroplasty had a modestly elevated short-term mortality (RR = 1.21, 95% CI = 1.06, 1.38). However, among those who survived 90 days, there was no detectable difference in mortality beyond 3 months post–hip fracture (Table 3).

Discussion

Based on a national sample of Medicare beneficiaries with hip fracture, we found only modest variation in the treatment across regions and races within the United States. Although there was a difference in post–hip fracture mortality between arthroplasty and internal fixation, the magnitude was small and limited to the first several postfracture months. White patients had the lowest postfracture mortality of the racial groups studied.

Although there appears to be consensus among US surgeons regarding management of femoral neck fractures, the observed treatment pattern differed dramatically from that in some regions of Sweden, where almost all femoral neck fractures receive internal fixation.[13] Because about 75% of femoral neck fractures are displaced,[14] this discrepancy almost certainly reflects differing opinions regarding optimal management for displaced femoral neck fractures.[15,16] These findings underscore this controversy and lend support for an evaluation of the outcomes of these alternative treatments.

The survival patterns we report here are comparable to those in several recently published series: the overall 30-day mortality ranged from 6% to 7% and the 1-year mortality ranged from 22% to 24%.[7,17–19] Several earlier studies have shown better short-term survival in patients with femoral neck fracture than in those with pertrochanteric fractures[5,6,19,20]; however, none of them reached statistical significance, possibly owing in part to limited sample size. Our study confirms that pertrochanteric fracture is associated with an elevated mortality even after adjusting for the effect of age and other risk factors.

It has been reported previously that Blacks have a higher mortality after hip fracture than Whites.[21] We show that these findings are independent of type of fracture and treatment, but only for the long-term mortality following the first 3 months postfracture. Could a difference in the severity of the hip fracture contribute to this difference in survival? Although we did not have information on the degree of trauma, the lack of a mortality differential in the first 90 days suggests that this is unlikely. A more plausible explanation for these long-term differences lies with the factors associated in general with a lower life expectancy among Blacks, such as lower socioeconomic status and limited access to health care.[22]

Our study shows nursing home residents to be less likely to have arthroplasty and more likely to suffer postfracture mortality, associations that were present in all census divisions. It is likely that these findings are owing to the poor health and psychosocial support of nursing home residents. Indeed, when comorbidity is deleted from our regression models, the effect of the nursing home appears substantially stronger. Previous studies have also shown that prefracture health and functional status, as well as psychosocial factors, are associated with outcomes following hip fracture.[23,24]

For femoral neck fractures, patients treated with other care had significantly higher mortality than those treated with arthroplasty or internal fixation. Since almost all patients with hip fractures are treated surgically except those who are severely ill, the elevated mortality among those treated with other care is almost certainly a consequence of patient selection. Survival following internal fixation was slightly better than that following arthroplasty, especially in the first several months postfracture—a finding that is consistent with those of several previous studies.[25–27] These differences could be owing to selection of healthier patients for internal fixation. An alternative explanation is that the higher short-term mortality following arthroplasty may be a consequence of factors such as the longer duration of anesthesia and the greater risk of blood loss during surgery.[26]

The validity of our study depends on the accuracy of the Medicare claims. The possibility of incomplete case ascertainment must be acknowledged, but it is unlikely to have affected our findings materially because hip fracture is among the most reliably coded hospital diagnoses.[8] To further improve the ascertainment, accuracy, and clinical relevance of the data extracted, we used both physician and hospital claims. Moreover, our follow-up was relatively complete. The vital

status of patients was based on Social Security Administration files, which have been found to identify more than 97% of known deaths with a false-positive rate of less than 0.1% among those over age 60.[28]

In summary, this study demonstrates that there is little geographic variation in the treatment for hip fractures within the United States. Differences in mortality between arthroplasty and internal fixation are modest and limited to the short term. Racial differences in survival postfracture seem to reflect general mortality trends. □

Lumbar Spine Surgery and Mortality among Medicare Beneficiaries, 1986

Neil B. Oldridge, PhD, Zhong Yuan, MD, James E. Stoll, MD, and Alfred R. Rimm, PhD

ABSTRACT

Objectives. The purpose of this study was to compare lumbar spine surgical procedures by age, gender, and number of comorbidities with respect to mortality in patients 65 years of age and older in the United States.

Methods. A 100% sample of the 1986 Medicare inpatient Health Care Financing Administration claims files databases involving lumbar spine surgical procedures was analyzed.

Results. Lumbar spine surgery in 34 418 patients (median age = 71 years) was associated with a significant increase in in-hospital and 1-year cumulative mortality only beyond 80 years of age. When adjusted for age, in-hospital and 1-year cumulative mortality with both decompression and excision procedures were significantly higher in men than in women. When adjusted for both age and gender, mortality increased significantly as the number of comorbidities increased.

Conclusions. With lumbar spine surgery in elderly patients, mortality did not significantly increase until 80 years of age and was consistently associated with decompression and excision, with male gender, and with an increase in number of comorbidities. (*Am J Public Health.* 1994;84: 1292–1298)

Introduction

Data on the effectiveness of lumbar spine surgery in elderly patients (those 65 years of age and older) are rare. We were able to identify few outcome studies that supported or negated Parrish's 1962 recommendation that age, at least up to 72 years, should not deprive patients of the benefits of surgery in the treatment of "lumbar disc syndrome" if the appropriate indications exist.[1] We were also able to identify only one randomized trial of surgery vs conservative care, that carried out by Weber[2] with 126 patients 22 to 55 years of age who had herniated lumbar discs. There was significant improvement at 1 year in those who had undergone surgery; by 4 years, however, the differences between surgery and conservative care were no longer significant. A literature search for low back pain and spine surgery citations in older patients identified nine articles published between 1987 and 1991 involving a total of 370 patients (mean age = 66.6 years; range = 45 to 89 years), approximately equal numbers of whom were male and female.[3–11] In a recent study based on a hospital discharge registry for the state of Washington, mortality, morbidity, and complications following lumbar spine procedures were demonstrated to increase with increasing age, particularly among those patients more than 64 years of age, and with more extensive surgery such as fusion and procedures associated with spinal arthrodesis.[12]

Increasingly, elderly people demand medical care, including surgery, not only to save life but to increase the quality of it. There are a number of treatments for low back pain with leg pain and refractory neurologic deficit, from conservative care to surgery. With the increasing sophistication and range of availabie treatment options, lumbar spine surgery for low back pain in the elderly will no doubt continue to be more prevalent in the future, accelerated by the increasing number of older patients and by the rising demand for surgery by older patients seeking an improved quality of life.

The 1989 National Health Interview Survey,[13] ranked orthopedic impairment as the most frequently reported chronic condition after arthritis and hearing impairment among patients 65 years of age and older. Back impairment, including intervertebral disc disorder, accounted for the largest proportion of orthopedic impairment,[13] and, after emphysema, it accounted for the most restricted activity and bed disability days.[14] Medical advances in anesthesia techniques, systems monitoring, and spine surgery instrumentation have made spinal surgery possible for an increasing number of older patients. However, the sheer size of the increase in surgery between 1979 and 1989 (e.g., a 204% increase in excision, a 232% increase in decompression, and a more than 350% increase in fusion[15,16]) is staggering, especially in light of the pau-

city of outcome results and the lack of randomized clinical trials in elderly patients with lumbar spine surgery for low back pain. The striking dichotomy between the relatively stable prevalence of back impairment and the more than twofold increase in lumbar spine surgery rates for patients 65 years old and older deserves close attention.

Development of guidelines for medical and surgical practices through assessment of patient outcomes demands evaluation of the effectiveness of medical and surgical interventions.[17] Access to medical care is becoming a more critical issue in medicine, particularly for elderly patients, who make up the most rapidly increasing population segment in the country.[18] As access becomes more important, analysis of existing national databases (e.g., the Health Care Financing Administration's [HCFA] Medicare databases) should provide useful information for policymakers, practitioners, and patients. In 1986, Medicare covered hospitalization expenses for about 95% of the US population 65 years of age and older.[19] Although patients included in these databases are not randomized to intervention, the databases have been used extensively,[20–28] and recent reports have demonstrated that they provide a valuable research tool.[29–33]

Our primary purpose in this descriptive epidemiological study was to gather data on in-hospital, 30-day postdischarge, and 1-year mortality following lumbar spine surgery in the elderly in the United States. We analyzed a 100% sample of the 1986 Medicare Provider Analysis and Review inpatient HCFA claims files databases for patients 65 years of age and older (eliminating a primary cancer diagnosis) undergoing surgery for low back pain. We then compared surgical procedures by age, gender, and number of comorbidities with respect to mortality.

Methods

The data for this study were derived from HCFA's 1986 Medicare Provider Analysis and Review inpatient claims files records, which include the nature of the patient's medical status and hospital stay from the hospital billing claim form filed with Medicare for the hospitalization (Medicare Part A, UB82 billing forms). The data fields include up to five International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) diagnosis codes; up to three procedure codes; the diagnostic-related group billing category claimed; dates of admission and discharge; and information on summary charges. Additional data are obtained from other HCFA and social security files on the level of Medicare reimbursement; patient (beneficiary) age, race, and sex; zip code of beneficiary's residence; and date of death of beneficiary. Date of death information is updated from the Social Security Master File at 3-month intervals for 2 years following the end of the reporting year (i.e., in this instance, through March 31, 1988). Population and annual mortality statistics for 1986 were obtained from data published by the US Bureau of the Census[34] and the National Center for Health Statistics.[35]

TABLE 1—Gender and Age in Medicare Patients Admitted with Diagnosis and Procedure for Anatomical Low Back Pain, 1986

	No.	Female, %	Median Age, y
First admission			
Spondylosis	74 528	66.6	75
Disc	40 698	63.1	72
Stenosis	68 604	68.1	74
Spondylolisthesis	1 982	75.1	75
Spondylosis plus disc	8 103	66.0	73
Spondylosis plus stenosis	10 311	70.9	75
Disc plus stenosis	11 053	65.3	72
Spondylosis, disc, stenosis	2 286	66.3	73
Total	217 565	66.1	73
First procedure			
Decompression	16 796	56.6	72
Excision	12 312	55.8	70
Fusion	550	70.2	72
Decompression plus excision	3 166	57.0	71
Fusion plus decompression	1 206	72.6	70
Fusion plus excision	388	63.9	70
Lumbar spine surgery	34 418	57.2	71
No surgery	181 204	66.8	73
Surgery for other reasons[a]	1 943	55.0	71

Note. Admissions involving a primary cancer diagnosis were excluded.
[a]Primarily fracture of vertebral column and other, multiple, ill-defined dislocations.

Hospitalization records for all 1986 Medicare patients 65 years of age or older were screened for the initial 1986 admission to the hospital with an anatomical low back pain diagnosis that may or may not have resulted in lumbar spine surgery. ICD-9-CM diagnostic codes for anatomical low back pain, excluding principal cervical and thoracic diagnoses and primary cancer diagnoses (codes 141.0 to 160.9, 162.0 to 172.9, and 174.0 to 209.89), indicated in at least one of the five diagnostic fields of the record included spondylosis (721.0 to 721.99), disc disease (722.0 to 722.99), spinal stenosis (724.0 to 724.99), and spondylolisthesis (738.4). The same hospitalization records were searched separately for an initial lumbar spine surgical procedure in 1986. Selection of lumbar spine surgery cases was based on the first 1986 file record with an ICD-9-CM procedure code indicated in at least one of the three procedure fields of the record: exploration and decompression (laminectomy) of spinal canal structures (03.00, 03.09), excision or destruction (discectomy) of intervertebral disc (80.5, 80.50, 80.51, 80.59), and spinal fusion (at one or more vertebral levels, with and without excision, decompression, or instrumentation) (81.00, 81.06, 81.07, 81.09). The two files were merged, and patients with lumbar spine surgery were grouped by 5-year age increments from 65 to 84 years, with all patients 85 years old and older constituting the last group.

Mortality was defined as occurring before discharge (in-hospital mortality), within 30 days of discharge (30-day postdischarge mortality), or within 1 year of the date of the first hospital admission (1-year mortality) for surgery for low back pain in 1986. Mortality for each procedure (i.e., excision, decompression, decompression plus excision, and fusion, including fusion combinations) and mortality by age group and gender were calculated with the respective number of patients undergoing surgery as the denominator. Fusion, fusion plus decompression, and fusion plus excision were combined in one

category for analysis purposes because their numbers alone by 5-year age group were small, making the interpretation of the analysis of procedure by age and gender difficult, and because significant differences in outcome do not differ with widely differing fusion procedures.[16] On the basis of data recorded at the time of the surgery admission, patients were assigned to diagnostic, or comorbidity, categories based on the ICD-9-CM diagnostic code fields. The relationships between the following factors were studied: age (in 5-year age groups starting at 65 years), gender, and comorbid diagnoses. The most frequently reported comorbidities (excluding cancers) were acute ischemic heart disease (ICD-9-CM codes 410 to 411.99), cerebrovascular disease (430 to 438.99), chronic heart failure (428 to 428.99, 402.01, 402.11, 402.91), diabetes (250 to 250.99), hepatic disease (571 to 572.99), hypertension (401 to 405.99), other heart disease (393 to 398, 412 to 414.99), psychiatric disease (290 to 290.99, 294 to 299.99), pulmonary disease (480 to 493.99, 496 to 496.9), and renal disease (582 to 583.99, 585 to 587.99).

Chi-square analyses were used to test for associations between mortality and a given factor or comorbidity. Analyses of variance were used in comparisons of mortality rates by age group and procedure for all patients 65 years of age and older in the United States admitted to the hospital and undergoing spine surgery for low back pain. In appropriate instances, the relative risk (RR, using the ratio of rates) of mortality in one vs another level of patient characteristic is reported. In order to examine the effects of comorbidity on mortality, patients were selected on the basis of 0, 1, 2, and 3 or more comorbid diagnoses. Multiple logistic regression analysis was used to study factors associated with in-hospital, 30-day postdischarge, and 1-year mortality.

Results

Among Medicare patients 65 years of age and older, there were 217,565 first hospital admissions (median age = 73 years) in 1986 involving a primary anatomical diagnosis of low back pain. Of the patients admitted, 144,692 were women (mean age = 75.8 years, SD = 7.3) and 72,873 were men (mean age = 73.9 years, SD = 6.7); the median age was lowest for patients with disc disease (Table 1). Also, 91.1% were White, 5.1% were Black, and 3.8% were of other races.

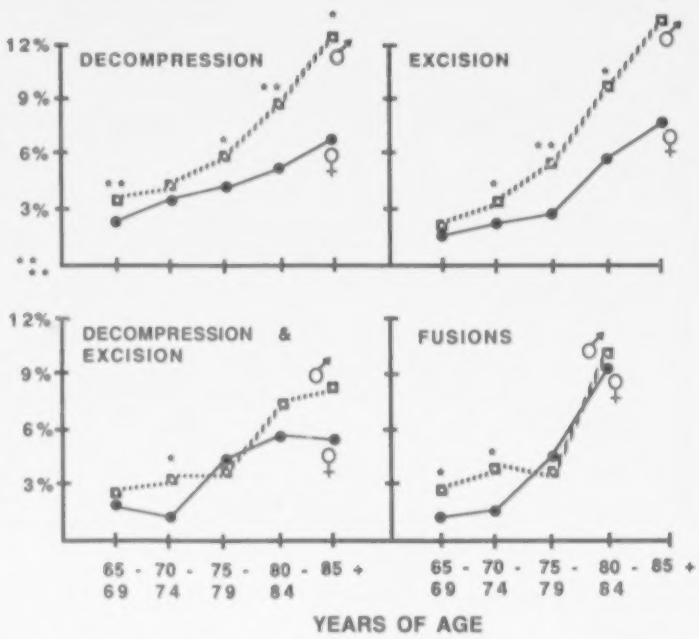
Procedures

There were 34 418 lumbar spine surgical procedures (first procedure in 1986) for low back pain among Medicare patients 65 years of age and older (median age = 71 years), 19 692 involving women (mean age = 72.3 years, SD = 5.4) and 14 726 involving men (mean age = 71.8 years, SD = 5.2). The median age was highest for those undergoing decompression and fusion procedures (Table 1). The proportion of women admitted to the hospital was 66.5%, in comparison with 57.2% of those with a procedure. Of the patients with a procedure, 92.1% were White, 3.8% were Black, and 4.1% were of other races. Patients 80 years of age and older with low back pain accounted for 29% of those who did not have surgery and 10% of those who did. There were 1943 patients who underwent an initial lumbar spine surgery procedure in 1986 but who did not meet the diagnostic eligibility criteria for low back pain; the reasons for surgery in these patients were primarily fracture of the vertebral column, benign neoplasms, and other, multiple, ill-defined dislocations (Table 1). These patients were excluded from the mortality analyses.

The mean length of stay with a procedure was 12.1 days (12.9 days for decompression, 11.4 days for excision, 14.5 days for fusion, 15.0 days for excision plus fusion, 14.0 days for decompression plus fusion, and 12.0 days for decompression plus excision). The estimated hospital charges for 1986 were as follows: $688.57 million for admissions not involving a subsequent surgical procedure (mean length of stay = 7.8 days, mean charge = $3800), $265.02 million for lumbar spine surgical procedures (mean charge = $7700, with fusions the highest at $11 400), and $34.20 million for lumbar spine surgery procedures not associated with a low back pain diagnosis (mean length of stay = 21.0 days, mean charge = $17 600). Thus, the total hospital charges for all 217 565 admissions amounted to an estimated $987.79 million.

Mortality

The in-hospital mortality rate among the 34 418 patients undergoing a first spine surgical procedure for low back pain in 1986 was 0.52% (0.72% in men vs 0.37% in women; $P < .001$). When adjusted for age, in-hospital mortality was higher in men than in women for decompression and for excision procedures ($P < .01$) (Table 2). In-hospital mortality with decompression and decompression plus excision procedures increased significantly at 85 years of age in both men and women, although numbers were small for the combined procedure; with excision, mortality increased significantly at 80



Note. □ = male; ● = female. *$P < .05$, **$P < .005$ (male vs female).

1 comorbidity	2.18	1.93, 2.45
2 comorbidities	4.03	3.46, 4.78
3 or more comorbidities	8.63	6.47, 12.08

Note. The relative risk for no comorbidity was 1.00. CI = confidence interval.

years of age only in women, and, with fusions, mortality also increased significantly at 80 years of age but only in men (Table 2). The highest in-hospital mortality for men was seen with decompression and decompression plus excision procedures; the highest mortality for women involved excision and decompression plus excision procedures.

The overall 30-day postdischarge mortality rate was 0.31%, (0.38% in men and 0.25% in women; $P < .05$). Age-adjusted, gender-specific 30-day postdischarge mortality was higher in men than women only for excision ($P < .025$) (Table 2). Thirty day postdischarge mortality increased ($P < .05$) at 85 years of age only in women and only with decompression and excision.

The 1-year mortality rate was 3.52% (4.38% in men vs 2.89% in women; $P < .001$). Age-adjusted, gender-specific 1-year mortality was significantly higher in men than women with decompression and excision ($P < .0001$) (Table 2). One-year mortality increased significantly at 80 years of age with excision and fusion procedures in both men and women; the age pattern for the other procedures was not as consistent, but the rates were higher in older subjects. The gender-specific 1-year mortality for each of the procedures is presented graphically in Figure 1; in all instances in which there were significant differences between the genders, men had the higher event rate. The relative risk for 1-year mortality with spinal surgery for low back pain, in comparison with the expected mortality in the US population 65 years old and older by 5-year age groups,[34] was less than 1.00 in more than 75% of the Age × Gender × Procedure cells (Table 3).

The univariate techniques used to identify associations between the various comorbidities identified in the UB82 billing forms and mortality showed significant relative risks of 2.00 and greater for in-hospital, 30-day postdischarge, and 1-year mortality in regard to acute ischemic disease (RRs = 32.9, 5.6, and 7.4, respectively), renal disease (RRs = 9.9, 7.5, and 9.1), other heart disease (RRs = 4.7, 2.0, and 2.0), and cerebrovascular disease (RRs = 3.2, 6.0, and 3.1). Pulmonary disease and congestive heart failure were significant for in-hospital (RRs = 3.8 and 3.3) and 1-year mortality (RRs = 2.1 and 3.0), while hepatic disease was significant for 30-day postdischarge (RR = 27.3) and for 1-year mortality (RR = 7.3). Hypertension was consistently protective (RRs = 0.57, 0.51, and 0.80 for in-hospital, 30-day postdischarge, and 1-year mortality, respectively).

The multiple logistic regression model was then used to determine the relationships between age- and gender-adjusted mortality and number of comorbidities. A relative risk of 1.00 was used for mortality observed in patients with no comorbidities listed; in-hospital, 30-day postdischarge, and 1-year mortality, as expected, increased with the number of comorbidities (Table 4).

Discussion

Although health services data derived from administrative billing information may be criticized when used for clinical decision making,[29,30,33] recent studies demonstrate that hospital billing records can, with careful planning (e.g., consideration of age, gender, and comorbidity) provide a valuable research tool.[29–33] While the accuracy of diagnostic and comorbidity coding remains a concern,[29,30,33] the coding of major surgical procedures in the Medicare claims databases is highly accurate, ranging from sensitivities of .88 to more than .95 for 10 of the 15 procedures examined and positive predictive values of .89 to more than .99 for 7 of the 15 procedures examined.[29] Medicare claims databases similar to those used in this study have been the basis of extensive seminal research in the field of health services.[19–21,23,24] Recently we used the same Medicare databases for reports involving hospital characteristics and mortality rates,[25] hip fracture,[26,27] and factors influencing coronary artery bypass surgery.[28]

In 1986, 217 565 Medicare beneficiaries 65 years of age and older were admitted to US hospitals with a diagnosis of anatomical low back pain and 34 418 underwent lumbar spine surgery. The cumulative 1-year mortality in patients with lumbar spine surgery was 3.52% (of which approximately 15% had occurred before discharge from hospital) and was significantly higher in men than in women. The age-adjusted 1-year mortality ranged from a low of 2.31% in women with fusion and fusion combination procedures to a high of 4.93% in men with decompression procedures. One-year mortality data for patients of comparable age with spinal surgery for low back pain are not available, but the expected US population rate of 3.61% for this age group[30] is similar to that observed here. On the other hand, comparable data in older patients undergoing spinal surgery for low back pain are available for in-hospital mortality rate; this rate was 0.52% in the present study and, again, significantly higher in men than in women, as previously reported by Deyo et al.[12]

The 80- to 85-year age range appears to be a threshold for a significant increase for both in-hospital and 1-year mortality, reinforcing the importance of factors other than age when selecting patients for spinal surgery. Ramirez and Thisted[37] reported an in-hospital mortality rate of 0.059% in patients over the age of 18 years undergoing lumbar discectomy, while Deyo and colleagues[12] reported an overall in-hospital mortality rate of 0.07%, increasing with age from 0.01% at 41 to 64 years, to 0.21% at 65 through 74 years, and 0.60% at 75 years and older. In the present study, the 0.28% in-hospital mortality rate with lumbar spine surgery for low back pain in patients 65 to 74 years of age was similar to that reported by Deyo et al. for patients in the same age range[12]; however, in those patients 75 years of age and older, the rate of 1.3% observed in this study was approximately twice that reported by Deyo et al. for patients of the same age.[12] The large difference between the overall in-hospital mortality reported by Ramirez et al.[37] and that reported here is due, in part, to the differences between

the studies with respect to the procedures considered for analysis and with respect to age (the patients included in the Ramirez study underwent lumbar discectomy and were 18 years of age and older[37]).

A desire for an improved quality of life on the patient's part may be the most important factor driving the increase in number of lumbar spinal procedures. Today the elderly live longer, healthier, and more active lives, and factors such as life expectancy, overall health status, and the ability of patients to tolerate the surgery and subsequent rehabilitation need to be considered when making treatment decisions. The importance of the discrepancy between functional and chronological age, and therefore the need to question age per se as an exclusionary criterion for surgery, has been reinforced in recent investigations of various surgical procedures (e.g., coronary bypass surgery in octogenarians[38] and nonagenarians[39]). Logically, increasing age and associated medical conditions, together with the stress of surgery, should be expected to result in increased mortality. However, appropriately selected patients 90 years of age and older do tolerate the stress of surgery relatively well,[39] although age bias might be more widespread than warranted, at least for elderly patients with either cancer[40,41] or heart disease.[38,42,43] The 1-year mortality rate among the 181 204 patients admitted with low back pain but without subsequent surgery was 10.01%. We can find no publications describing the treatment and outcome of hospitalization in elderly patients who are admitted to the hospital for low back pain but do not undergo lumbar spine surgery. However, the difference in mortality in favor of patients undergoing surgery is probably associated with a patient selection bias inherent in making decisions about older patients as candidates for lumbar spine surgery. When patient age was less than 75 years, the relative risk for 1-year mortality, in comparison with the expected mortality in the US population 65 years old and older,[34] was greater than 1.00 in 25% of the Age × Gender × Procedure cells; however, it was greater than 1.00 in only 12.5% of the cells when patient age was 75 years or older. Patient selection, particularly with increasing age, appears to be as, or more, important than the procedure when considering patient outcome. In the present study, at least up to the age of 80 years, the low mortality associated with lumbar spinal procedures for low back pain extends the relevance of Parrish's 1962 recommendation that, if the appropriate indications exist, age per se should not deprive patients of the benefits of surgery in the treatment of low back pain.[1]

While the age effect per se, at least between 65 and 80 years, in those undergoing lumbar spine surgery does not appear to greatly increase the risk of death after such surgery, the number of comorbid conditions does increase this risk, supporting observations with other surgical procedures in the elderly.[12,38,39] The extent to which comorbid conditions in this study affected mortality was quite marked; the relative risk for in-hospital mortality increased from 1.00 for no coexistent comorbidity to 21.59 with three or more comorbidities; the corresponding 30-day postdischarge risk was 10.49, and the 1-year mortality was 8.63. Factors that probably contribute to the increasing risk (particularly in-hospital and 30-day postdischarge) with lumbar spine surgery seen at 80 years of age and older are an increasingly weaker bone stock and greater neural involvement, an increasingly high likelihood of serious comorbidities, and a poorer physical status (per the American Society of Anesthesiology classification). While the HCFA billing records are not as reliable with respect to comorbidities as they are with respect to surgical procedures,[29,33] the relative risk for in-hospital, 30-day, and 1-year mortality, as might be expected, was significantly increased with one or more comorbidity, particularly with coexistent ischemic heart and renal disease. The paradoxical protective effect of hypertension observed in this study has been reported previously, but without a definitive explanation.[33]

In summary, this study of the large HCFA claims files for 1986 helps define age and gender demographics related to low back pain and outcome following lumbar spine surgery in all elderly Medicare beneficiaries in the United States. In 34 418 elderly patients who underwent lumbar spine surgery, male gender was associated with higher in-hospital and 1-year age-adjusted mortality than that observed in women. Also, 80 years of age appeared to be a threshold for increased mortality, and, as expected, increasing numbers of comorbid conditions were associated with an increased risk of age-adjusted mortality. An important limitation inherent in this Medicare database is the lack of data on the impact of lumbar spinal surgery for low back pain on functional status and the health-related quality of life in the elderly. However, the low mortality associated with lumbar spinal procedures for low back pain, at least in patients up to 80 years of age, extends the relevance of Parrish's[1] aforementioned recommendation. □

Acknowledgments

This study was supported by grant 1-R15-AG09005-01 from the Institute of Aging, National Institutes of Health.

We would like to thank Dr M. Gottlieb for his assistance in the early phases of the study.

Supplement on Exercise and Aging Available

"Exercise and Aging: Prescription for Wellness," a supplement to the May 1994 issue of *Southern Medical Journal*, is available from the Southern Medical Association. The supplement reflects the contents of a symposium held in Gainesville, Fla, in September 1992, for the purpose of updating health professionals on developments in the field of basic and applied exercise science for both healthy and chronically ill elderly persons.

Topics covered in the supplement include the effects of exercise on age and disease, skeletal muscle function, bones, metabolism, arthritis, and the nervous and cardiac systems; respiratory and spinal considerations; and motivating and establishing programs for the elderly.

Diet, Indicators of Kidney Disease, and Later Mortality among Older Persons in the NHANES I Epidemiologic Follow-Up Study

Johanna T. Dwyer, DSc, RD, Jennifer H. Madans, PhD, Barry Turnbull, PhD, Joan Cornoni-Huntley, PhD, Connie Dresser, RDPH, LN, Donald F. Everett, MA, and Ronald D. Perrone, MD

ABSTRACT

Objectives. The purpose of this study was to determine whether diet adversely affected survival among 2572 older persons with indicators of kidney disease in a population-based cohort. Average follow-up time for survivors, of whom 1453 (57%) had died at analysis, was 14.5 years.

Methods. Kidney disease indicators were a "yes" response to "Has a doctor ever told you that you have kidney disease or renal stones?" and/or trace or greater amounts of protein in urine. Dietary protein intakes were calculated from 24-hour recalls.

Results. Cox proportional hazards models were used, stratified by sex, with age, body mass index, blood pressure, education, smoking status, total caloric intake, and diabetes mellitus as covariates. Relative risk of total mortality with an additional 15 g of protein per day was 1.25 (95% confidence interval [CI] = 1.09, 1.42) among White men with kidney disease indicators, vs 1.00 (95% CI = 0.95, 1.06) among those without them; relative risks of renal-related mortality were 1.32 (95% CI = 0.97, 1.79) and 0.95 (95% CI = 0.81, 1.11), respectively. No significant differences were found for White women.

Conclusions. Once chronic renal disease is present, diet may be associated with earlier mortality in White males. (*Am J Public Health.* 1994;84: 1299–1303)

Introduction

Chronic kidney disease leads to increased mortality and morbidity. Kidney disease, kidney stones, and biochemical signs of kidney pathology, such as protein in the urine, increase risks of chronic renal insufficiency, an incurable condition that frequently progresses to end-stage renal disease.[1] End-stage renal disease is fatal unless dialysis or transplantation is available. Even with these therapies, premature atherosclerosis, stroke, hypertension, and other complications reduce life expectancy.[2]

High blood pressure does, and high protein intakes may, speed the rate of progression of chronic renal insufficiency,[3] and protein restriction may slow it.[4–10]

We analyzed data from the population-based National Health and Nutrition Examination Survey I (NHANES I)[11,12] and the NHANES I Epidemiologic Follow-Up Study[13–15] to determine whether diet adversely affected survival among Whites aged 65 years or older who had indicators of kidney disease at the time of baseline examination and whether the nature of the relationship differed for those with and without kidney disease. These data sets were collected before any dietary adjustments were made for individuals with early chronic renal insufficiency.[16,17]

Methods

The NHANES I, a probability sample of the civilian noninstitutionalized population of the United States,[11] was conducted from 1971 through 1974 and augmented by an additional national sample in 1974 and 1975.[18] Information on disease status, demographic characteristics, dietary intake, and other covariates from NHANES I was used for the analysis.[15] From 1982 through 1984, with additional waves in 1986 and 1987, the NHANES I Epidemiologic Follow-Up Study recontacted NHANES I participants who were 25 years of age and older at their first interview (or suitable proxies for decedents).[13–15] Vital status through 1987 is known for 96% of the original cohort, and death certificates have been obtained for 96% of the decedents. Average length of follow-up for survivors is 14.5 years.

This study was limited to White persons 65–74 years of age at baseline (1339 men and 1497 women) for whom nutrition information was collected. Whites were studied because of an insufficient number of members of other ethnic groups for ethnicity-specific analyses. Those older than 65 years were studied

TABLE 1—Study Population by Sex and by Kidney Disease Indicators at Baseline

Kidney Disease Indicator at Baseline	Percentage	
	Men (n = 1231)	Women (n = 1341)
Doctor's statement		
Currently has disease	3.6	4.1
Does not have disease	96.4	95.9
Proteinuria		
None	96.0	97.8
Trace	2.3	1.3
Greater than trace	1.7	0.9
Kidney disease risk case status	7.4	6.3

because kidney disease is more prevalent in such persons. Ten men and 17 women were lost to follow-up, and an additional 98 men and 139 women were eliminated from the analysis because of missing data on covariates, resulting in a sample size of 1231 White men and 1341 White women aged 65–74 years at baseline.

Table 1 describes the study population according to disease status. Because NHANES I did not include a definitive measure of kidney disease, either of two indicators of kidney disease was used to identify cases. Persons who responded "yes" to both of the following questions were counted as case subjects: "Has a doctor ever told you that you have any of the following conditions (kidney disease *or* renal stone)? If so, do you still have it?" Persons with a laboratory determination of protein in the urine were also considered to have kidney disease. Protein in the urine was ascertained from urine specimens provided by participants in the mobile examination center by using a urine dipstick.[17] Persons who had a positive result (trace amount or greater, i.e., at least 15 mg of albumin/100 mL) on the dipstick were defined as having kidney disease. One hundred seventy-five cases of kidney disease (91 men and 84 women) were identified by at least one of these criteria. Only two subjects reported kidney disease and had proteinuria.

We also performed analyses using a definition of kidney disease based solely on proteinuria, because substantial, constant, continuous proteinuria is a sensitive, specific indicator of kidney disease that is strongly associated with both morbidity and mortality.[20,21] Trace or low levels of proteinuria, such as those we included as indicators of kidney disease, are relatively nonspecific and may result from many causes, including fever, concentrated urine samples, benign forms of glomeruloproteinuria,[22,23] infection, tubulointerstitial disease, exercise, and other factors.[24,25] Because the dipstick measure of urinary protein is semiquantitative, the midpoint for the protein range of each category was assigned (e.g., trace = 22.5; 1+ = 65; 2+ = 200; 3+ = 650; and 4 = 1000 mg of protein/dL). We further refined the proteinuria measure by calculating the ratio of urinary protein (mg/dL) to creatinine (mg/dL) in order to rule out the possibility that high numbers of false-positives resulted from concentrated urine. Ratios equal to or greater than 0.2 were used to indicate disease. By this definition, 27 men and 15 women had kidney disease.

Protein and other nutrient intakes were calculated from the 24-hour recall of food intake collected during NHANES I. Those who consumed the highest amounts of protein based on the 24-hour recall also consumed the largest number of servings of animal protein–rich foods as indicated on a nonquantitative food frequency questionnaire that was also collected (data not shown). Protein intakes were highly and significantly ($P < .001$ level or less) intercorrelated with other nutrients of possible interest ($r = 0.839$ with phosphorus, 0.566 with calcium, 0.581 with total fat, 0.629 with saturated fat, and 0.776 with calories). Although we used calories as a covariate in the analysis, it was not possible to definitively ascertain if the observed effects were due to protein alone or to one of these associated constituents.

We obtained mortality outcomes through 1987 using all three waves of follow-up. We obtained death certificates for all but 37 (16 men and 21 women) of the 1453 reported deaths and coded the underlying cause of death from them with the *International Classification of Diseases*, 9th revision (ICD-9), using standard procedures.[26] In this report, mortality was analyzed for all causes, as well as for renal and renal-related diseases (e.g., ICD-9 condition codes 580, 599, 016, 179–189, 250, 401–404, and 441–448). Renal-related condition was defined as any disease of the kidney, plus hypertension and its complications, including hypertensive, atherosclerotic cardiac and vascular disease, because of the well-known associations between kidney disease, hypertension, and premature atherosclerosis.[1] Ninety men and 61 women died of kidney-related causes.

Covariates included age, education, body mass index, blood pressure, protein intake, history of diabetes, smoking status, and total caloric intake measured by using standardized procedures specified in the NHANES manual[19] and described elsewhere.[11,12,18] All of these are associated with mortality and possibly with kidney disease.[1,2,3,27]

Age-adjusted death rates were calculated by using the direct method, with the total NHANES I population as the standard population. Estimates of the risk of death and associated confidence intervals (CIs) were derived from Cox proportional hazards regression models computed with the PHGLM procedure in the Statistical Analysis System.[28] Models were estimated separately for men and women. Interaction terms involving kidney disease status and protein intake were included in the models to test the hypothesis that the effect of protein intake on survival is different among those with kidney disease compared with those without the disease and to estimate risk for those with or without a kidney disease. To assess the effect of the complex survey design on the results, weighted person-time logistic regression analyses were done.[28,29] Previous analyses of the NHANES I Epidemiologic Follow-Up Study data indicated that clustering and stratification have only minimal effects on the estimates.[30,31] Because the results of the weighted analyses were consistent with the unweighted estimates, only the estimates from the unweighted Cox regression models are presented.

Results

Table 2 presents characteristics of the study population at baseline. Male case subjects were similar to noncase subjects except that White men with indicators of kidney disease were more likely to report histories of high blood pressure and diabetes. In women, case subjects were older, were heavier as measured by body mass index, and had lower caloric intakes, higher systolic blood pressures, and lower educational levels than those without kidney disease. Diastolic blood pressure, history of high blood

TABLE 3—Number of Deaths and Age-Adjusted Death Rates per 1000 Years of Follow-Up, by Cause, Kidney Disease Case Status at Baseline, and Sex

	Death from All Causes		Kidney-Related Deaths [a]	
Case Status	No.	Rate per 1000 y	No.	Rate per 1000 y
Men				
Case	71	95.40	14	18.79
Noncase	751	66.72	76	6.76
Women				
Case	48	53.87	8	8.98
Noncase	583	39.62	53	3.62

[a]Included ICD-9 causes of death as follows (with no exclusions for comorbid conditions): codes 580–583 (nephrotic syndrome, chronic glomerulonephritis, nephrosis, etc.); codes 584–589 (other types of renal disease); codes 590–599 (other diseases of the urinary system); code 016 (tuberculosis of kidney and genitourinary system); codes 179–189 (malignant neoplasms of genitals and urinary organs); code 250 (diabetes mellitus); codes 401–404 (hypertension, hypertensive heart or/and renal disease); and codes 441–448 (other diseases of artenes, arterioles, and capillaries).

pressure, weight, and history of diabetes were also greater among case subjects.

Table 3 describes the cohort's mortality experience. Men with kidney disease were 40% more likely to die during the follow-up period and over two and one-half times more likely to die of renal-related disease than were noncase subjects. Women with kidney disease were also 36% more likely to die during follow-up and two and one-half times as likely to die from renal-related disease as noncase subjects.

Table 4 presents the regression coefficients and standard errors from the Cox proportional hazards models for all-cause and renal-related mortality. Among men, all covariates (except systolic blood pressure and education) were significantly related to all-cause mortality. Only systolic blood pressure and diabetes were associated with renal-related mortality, however. In men, there was a significant interaction between kidney disease status and protein, indicating that the effect of protein intake on mortality varied by disease status at baseline. To illustrate this effect, we calculated the relative risks (RRs) and associated confidence intervals (CIs) for an increase in protein intake of 15 g per day for those with and without kidney disease. The effect for those with kidney disease was calculated by using the Cox model coefficients for protein intake and for the interaction term where protein intake was evaluated at any intake amount and then at that amount plus 15 g. The effect for those without kidney disease is only a function of the coefficient for protein intake because the interaction term drops out of the model for this group.

The relative risk of total mortality associated with a 15-g increase in protein intake daily among men with kidney disease indicators was 1.25 (95% CI = 1.09, 1.42), whereas the risk among the nondiseased was 1.00 (95% CI = 0.95, 1.06). A similar effect was found for renal-related mortality (RR = 1.32 [95% CI = 0.97, 1.79] vs RR = 0.95 [95% CI = 0.81, 1.11], respectively). Models stratified on kidney disease status produced very similar effects of protein intake on mortality. In addition, the stratified models were re-estimated with protein intake categorized into quartiles. These analyses provided no evidence of a nonlinear relationship between intake and mortality among case or noncase subjects.

The results for women were quite different. Regardless of their status with respect to kidney disease indicators, protein intake was not associated with either total (RR = 1.12 [95% CI = 0.92, 1.36] with disease vs RR = 1.04 [95% CI = 0.96, 1.11] without disease) or renal-related mortality (RR = 1.16 [CI = 0.72, 1.86] with disease vs RR = 1.06 [95% CI = 0.85, 1.32] without disease).

Because fat consumption (total or saturated) and protein intake are highly related, measures of fat consumption were included in the model to test whether the observed relationship between protein and mortality was confounded by fat intake. No significant interaction between fat and kidney disease was observed for either sex. However, the effect of protein remained significant for men with kidney disease.

We repeated the analysis using the more stringent urinary protein/urinary creatinine ratio definition of kidney disease. Although the interaction between kidney disease status and protein intake

*$P < .05$; **$P < .01$.

was at the marginally significant level for total mortality for men, the magnitude of the effect of an increase in protein intake found in this model was similar to that found in the model based on the more liberal definition of case status. No change in mortality was associated with protein intake for noncase subjects. Among women, significant interactions were not found for total or renal-related mortality, but the number of cases in these latter models was very small.

Discussion

Persons with kidney disease experienced increased mortality, but the possible effects of diet on this association are not well documented.[1] This analysis found a relationship between protein intake and mortality for White males with kidney disease that remained after accounting for possible confounders, including history of diabetes, high blood pressure, and total or saturated fat intake. There is no reason to suspect recall bias in the reporting of diet by disease status or by disease severity.

The study does have several limitations. Twenty-four–hour recalls are relatively insensitive measures of long-term nutrient intake.[32,33] However, those who consumed the highest amount of protein based on the 24-hour recall also consumed the largest number of servings of animal protein–rich foods on a nonquantitative food frequency questionnaire also collected in NHANES I. Underreporting of intakes is common[34] and was likely in this study because reported energy intakes were very low compared with standards.[35–37]

Possibly those classified as case subjects did not have kidney disease, or true cases were missed. The strictest definition of case status limited the first type of misclassification. Analysis with a definition of renal disease based on urinary protein/creatinine ratios identified a smaller numbers of persons (2.2% of men and 1.2% of women), yet results for men were in the same direction as and similar in magnitude to those found when the definition of case status was based on proteinuria and self-report. Other nonrenal causes of proteinuria could not be ruled out, however, and these remain a potential source of false-positives.

We think it unlikely that we failed to identify many patients with renal disease (false-negatives). Either proteinuria or self-report could result in case status. Even those suffering from undiagnosed disease were identified as case subjects if they exhibited proteinuria. Self-report of disease was more likely to have been subject to overreporting errors because it included renal stones (which are not always indicative of renal disease), and some individuals may have confused urinary tract infections with kidney disease.

As for the gender differences found in renal disease indicators and mortality, the definition of kidney disease (which relied on both self-report and proteinuria) may be a less reliable indicator of kidney disease in women, possibly accounting for the lack of association in women. More women than men reported that a doctor had told them they had kidney disease, whereas only half as many women as men had proteinuria in any amount (Table 1). Women, who are more likely to have urinary tract infections than men, may have confused these infections with kidney disease and overreported disease status. Urinary tract infections may also yield a positive dipstick test for low-level proteinuria, but uncomplicated urinary tract infections rarely give rise to later kidney disease.[24] Possibly kidney disease has a different course in men than in women; women are less likely to progress to end-stage renal disease than men, perhaps because they have lower morbidity rates of kidney disease–associated conditions such as hypertension, atherosclerosis, and arteriosclerosis.[1]

Conclusion

If renal disease indicators are present, dietary factors may play a role in heightening mortality in White males 65 years and older. Our study's statistical power and precision were limited due to the small number of persons with kidney disease, and it could not adequately control for comorbidities and unmeasured confounders. Additional analyses are needed to confirm these findings. □

Emotional Disability Days: Prevalence and Predictors

ABSTRACT

This study considered days missed from work or usual activities for emotional reasons associated with a range of specific psychopathologic disorders, psychosocial distress, and persons found to be asymptomatic. Analyses were performed with the presence or absence of emotional disability days as the dependent variable using logistic regression. The effects of specific mental disorders were compared with the effects of chronic physical conditions for labor force participants and for the total population. The odds ratio (and 95% confidence interval) for subjects with major depressive disorder was 27.8 (6.93, 108.96); for panic disorder, 21.1 (2.25, 198.44); and for schizophrenia, 17.8 (1.73, 182.99). Workplace adjustments for persons with psychopathology are encouraged. (*Am J Public Health*. 1994;84:1304–1307)

Anthony C. Kouzis, PhD, and William W. Eaton, PhD

Introduction

Beyond the immediate tragedy of emotional or mental illness is associated impairment as measured by days lost from work, disability, a reduced sense of well-being, and the need for health care. Functional status—that is, the capacity to perform tasks and activities—is a primary concern of patients, their families, and physicians. Restricted activity days experienced by persons in a year is an important measure of functioning status and well-being.[1-4]

Previous studies have focused on estimated associations of various measures of functioning with specific chronic medical conditions; few associations have been made with patients experiencing distress or psychopathology.[5] Wells et al.[6] and Broadhead et al.[7] have shown that depression and disability from work are related. A positive relationship has been found between physical illness and depression or psychological distress in some[8-14] but not all studies.[15,16] Thus, depression might be related to disability because it is associated with nonpsychiatric medical conditions.

In this research report, we consider days missed from work or usual activities for emotional reasons ("emotional disability days") associated with a range of specific psychopathological disorders and psychosocial distress. We assess and adjust for the influence of sociodemographic characteristics on these relationships, and we compare subjects who are in the labor force full time with the total population.

Methods

Study Sample

The study sample was drawn from the Eastern Baltimore Mental Health Survey conducted during 1981 as part of the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area Program.[17-20] It has recently been reported that East Baltimore has the highest rates of premature disability and death in the state.[21] This paper reports analyses from The Johns Hopkins University site of the NIMH program, which included three contiguous mental health catchment areas with an adult population of approximately 175 000. The data include information on 3481 individuals originally identified through a probability sample of adult household residents. The response rate was 78%.[22] Details concerning the characteristics of this population have been presented elsewhere.[17,18]

Measurement

Each participant in the survey underwent a 90-minute interview that included the NIMH Diagnostic Interview Schedule (DIS), which was scored to reflect diagnoses from the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition (DSM-III) (hence the label "DIS/DSM-III disorder").[23] Symptoms were counted only if they met the severity criteria of the DIS and were not explained by physical illness, medications, alcohol, or other drug use. This report focuses on disorders reported as present within the 6 months prior to interview.

The authors are with the Department of Mental Hygiene, Johns Hopkins University School of Hygiene and Public Health, Baltimore, Md.

This paper was accepted November 12, 1993.

The Baltimore site included the General Health Questionnaire to measure distress that might not be connected to a specific mental disorder.[24] The standard threshold of four or more was used to define those in the sample considered to be at "high distress."

Specific physical health conditions included asthma, high sugar or diabetes, heart trouble, high blood pressure, arthritis or rheumatism, and trouble breathing. Respondents were also asked if they had ever had a stroke and/or cancer.[25]

Respondents in the interview were asked, "During the last three months, were there any times when you were kept from your work, school or usual activities for at least one whole day because of an injury or because you weren't feeling well?" Those responding affirmatively were asked, "Were you kept from your usual activities because of an illness or physical condition? an emotional problem or trouble with your nerves?" For this study, days missed from work because of emotional problems and physical illness were analyzed separately. As in the Health Interview surveys, 3 months was selected as our recall period, a compromise offering an adequate number of responses and necessary recency.

Full-time employment status was ascertained by asking respondents what they were doing during most of the previous week (as in the Labor Force surveys). Analyses reported in the tables below focus on the 1463 respondents in the labor force at the time. Weighted data are used in our analyses and reported in the text and tables owing to the multistage sampling procedures of the Epidemiologic Catchment Area Program.[26,27]

Results

There is no striking variation according to sociodemographic variables in the percentage of respondents with emotional disability days (Table 1); however, it is notable that those with the least education and those without private insurance have the most absences from work—about 5%. After adjusting for all the personal characteristics, the odds of having an emotional disability day are presented in the far right column of Table 1. However, these were not significant. Household income was entered in regression analyses, but it is not included in the model in Table 2 because it was not significant and because more than 10% of the respondents failed to answer this item.

TABLE 1—Predictors of Emotional Disability Days: Estimates for the Labor Force Population of East Baltimore

	Sample, % (n = 1463)[a]	% Having Emotional Disability Days	Adjusted Odds of Having Emotional Disability Days	95% Confidence Interval
Sex				
Male	49	3.0	1.00

[a]In prior 6 months.
[b]In prior 3 months.
[c]Adjusted for age, education, marital status, race, sex, and health insurance.
[d]In prior several weeks.

Table 2 presents the percentage of those with at least 1 disability day for emotional or mental reasons by type of psychopathology, and the association of psychopathology with emotional disability. The comparison groups for the spe-

cific psychiatric disorders were those not meeting criteria for that specific disorder only. Persons with no DIS/DSM-III disorder were the comparison group for those with any DIS/DSM-III disorder.[28]

The most notable finding is the large percentage of subjects with DIS/DSM-III depressive disorders and panic disorders who reported a disability day owing to emotional reasons (44% each). Closely following are those with schizophrenia (40%). In contrast, among those who did not meet the criteria for any DIS disorder, only 2% reported an emotional disability day.

As the number of disability days was highly skewed, analyses were performed using logistic regression, with the presence or absence of disability days as the dependent variable.[29,30] The association of type of psychopathology with emotional disability is also shown in Table 2. Subjects suffering from major depression had the greatest odds of missing work (odds ratio [OR] = 27.8; 95% confidence interval [CI] = 6.93, 108.96). This was closely followed by those with a panic disorder (OR = 21.1; 95% CI = 2.25, 198.44). Schizophrenics had 18 times the odds of missing work for an emotional problem (OR = 17.8; 95% CI = 1.73, 182.99) compared with those without such a disorder. Those with an alcohol diagnosis were 11 times as likely to miss work at least 1 day (OR = 10.9; 95% CI = 3.42, 34.91). The crude odds ratios differ trivially. The large confidence intervals caution us regarding the possible stability of these findings.

The mean days absent from work for an emotional reason range from 3.2 to 9.4. Depression is associated with the greatest number of absences ($\bar{X}$ = 9.4 days, SD = 6.74), followed by high distress ($\bar{X}$ = 7 days, SD = 6.40). The mean for depression is greater than that owing to all conditions except cancer and cardiovascular problems.

The association of psychopathological disorders with absences from work owing to emotional reasons for the entire population was also examined. The odds ratios for those with panic disorders were 27 times greater, followed by only 9 times greater odds for major depressives. The pattern of other results was similar for the labor force group and the total population.

Discussion

Mental disorder has a strong association with missing days from work among those in the labor force. Subjects experiencing a major depressive disorder had the strongest association with disability as they showed a 27 times greater likelihood of being disabled from participating in work activities. Subjects with a diagnosis of panic disorder followed closely. The effects of sociodemographic characteristics are not critical to an understanding of the determinants of work absences.

Nagi differentiated the vocationally disabled from the vocationally nondisabled in that the latter were able to make job adjustments either on their own or with their employers.[31] Given the high prevalence of emotional disorders, greater concern, a more "reasonable accommodation,"[32,33] and continuous supportive employment services may be warranted.[9] Rising costs of services for morbidity and associated disability have focused attention on disabilities and the quality of life at the middle and later stages of life.[34,35] Our results point to the possibility of making adjustments for the emotionally handicapped as is currently done for the physically handicapped.[36,37] □

Acknowledgments

This analysis was supported by NIMH grant MH 47447 and MH 14592.

The ECA Program is a series of five epidemiological research studies performed by independent research teams in collaboration with staff of the division of Biometry and Epidemiology of the National Institute of Mental Health (NIMH). During the period of data collection, the program was supported by cooperative agreements. The NIMH principal collaborators were Darrel A. Regier, MD, Ben Z. Locke, MSPH, William W. Eaton, PhD (October 1, 1978, through October 1, 1983), and Jack Burke, MD (October 1, 1983, through March 1, 1987). The NIMH project officers were Carl A. Taube, PhD, and William Huber. The principal investigators and co-investigators from the five sites were Jerome K. Myers, PhD, Myrna M. Weissman, PhD, and Gary L. Tischler, MD, of Yale University, New Haven, Conn (U01 MH 33870); Morton Kramer, ScD, Ernest Gruenberg, MD, DPH, and Sam Shapiro, MS, of The Johns Hopkins University, Baltimore, Md (U01 MH 33870); Lee N. Robins, PhD, and John Helzer, MD, of Washington University, St. Louis, Mo (U01 MH 33883); Dan Blazer, MD, and Linda George, PhD, of Duke University, Durham, NC (U01 MH 35386); and Marvin Karno, MD, Richard L. Hough, PhD, Javier I. Escobar, MD, M. Audrey Burnam, PhD, and Diane Timbers, PhD, of UCLA (U01 MH 35865).

We thank the editor and two anonymous reviewers for their criticisms.

The Prevalence and Demographic Predictors of Illicit and Licit Drug Use among Lesbians and Gay Men

William F. Skinner, PhD

ABSTRACT

Studies on illicit and licit drug use among homosexuals of both sexes have focused primarily on gay men, used limited drug measures, and been conducted in cities known for large homosexual populations. This paper examines (1) the prevalence of 12 illicit and licit drugs by sex and age group and (2) the demographic predictors of past-year frequency of marijuana, alcohol, and cigarette use. Organizational mailing lists were used to collect self-report data on 455 homosexuals living in a southern state. Differences were found between gay men and lesbians in the use of specific substances and in the demographic predictors of drug use. (*Am J Public Health.* 1994; 84:1307–1310)

Introduction

Early research on illicit and licit drug use by homosexuals has primarily examined the prevalence of alcohol use and abuse using small, opportunistic samples.[1–13] Only within the last decade have studies begun to report both drug and alcohol use among larger and more representative samples.[14–19] However, most of this research has excluded lesbians, employed limited drug use measures, and been conducted in large cities known for their large homosexual populations (e.g., San Francisco). Little is known about the full extent of illicit and licit drug use among gay men and lesbians living in smaller cities.

This paper presents selected data from the Trilogy Project, a study of self-reported illicit and licit drug use among homosexuals of both sexes from two metropolitan areas in a southern state. Two issues are examined: (1) lifetime, past-year, and past-month age-specific prevalence of use of six illicit and two licit "recreational" drugs (alcohol and cigarettes) as well as the nonmedical use of four psychotherapeutic drugs by age; and (2) demographic predictors of reported frequency of use over the past year of marijuana, alcohol, and cigarettes—the three drugs most commonly used by both lesbians and gay men. Further data are reported elsewhere.[20]

Methods

Sample and Procedures

Respondents were self-defined homosexuals living in and around the two

*Differences in proportion between gay men and lesbians significant at .05 level.

largest cities located in a southern state. Participants were sampled by means of mailing lists from lesbian and gay organizations. A total of 455 respondents—190 (41.8%) lesbians and 265 (58.2%) gay men—completed the survey. This represents a 51.9% response rate overall. Mean age respective to each group was 36.4 and 37.4 years and mean years of education were 15.1 and 15.3 years. The majority of lesbians (92.3%) and gay men (94.1%) were White.

Within the context of research on lesbian and gay issues, the response rate, while low, is among the highest, and the coverage of illicit and licit drug use is among the most comprehensive reported to date.[13,16-19]

Measures

The drug use prevalence rates were calculated from responses to the question, "When was the most recent time you used [marijuana or hash], etc.?" The response categories were (1) never, (2) within the past week, (3) within the past month, (4) within the past year, (5) from 1 to 5 years ago, (6) from 5 to 10 years ago, and (7) 10 or more years ago. Past-year frequency of marijuana, alcohol, and cigarette use was measured by the question, "How often in the past year have you used [marijuana or hash], etc.?" Here the response categories were (1) never, (2) one to five times in the past year, (3) one to two times a month, (4) several times a month, (5) 1–2 days a week, and (6) daily or almost daily. These drugs were selected because they were the most common drugs used by both groups and had the largest variances. All drug questions were taken from the 1988 National Household Survey on Drug Abuse.[21]

Age was measured in number of years, and education was measured in

number of years of schooling. Personal income was categorized by (1) no personal income, (2) under $5000, (3) $5000 to $6999, (4) $7000 to $8999, (5) $9000 to $11 999, (6) $12 000 to $14 999, (7) $15 000 to $19 999, (8) $20 000 to $24 999, (9) $25 000 to $29 999, (10) $30 000 to $39 999, (11) $40 000 to $50 000, and (12) more than $50 000; household location was indicated by (1) rural, (2) town (under 10 000), (3) small city (10 000 to 100 000), (4) suburb, and (5) city (more than 100 000); and relationship status was measured by (0) single and (1) in relationship.

Statistical Procedures

To determine statistical differences in drug use between gay men and lesbians, a *z* test for differences in proportions for two samples was used. Ordinary least squares regression procedures were used to estimate the standardized regression coefficients.

Results

Prevalence of Illicit and Licit Drug Use

The prevalence of illicit and licit drug use for different age groups was similar for gay men and lesbians (Table 1). For inhalants and cigarettes, however, significant differences between gay men and lesbians occurred consistently: inhalant use was more prevalent among gay men and cigarette use was more prevalent among lesbians. Past-year and past-month use of any illicit drug, stimulants, and sedatives differed significantly between gay men and lesbians over age 35. The least prevalent drugs were crack and heroin.

Demographic Predictors of Marijuana, Alcohol, and Cigarettes

Linear multiple regression analysis indicates that for both groups, demographic predictors accounted for the most variance in cigarette use (Table 2). For lesbians, the frequency of marijuana use was significantly reduced with age and the frequency of cigarette use was significantly reduced with education; however, none of the demographic variables was a significant predictor of alcohol use. For gay men, education was important in reducing the frequency of both marijuana and cigarette use; living in urban areas increased the frequency of cigarette use; and income, household location, and relationship status significantly increased the frequency of alcohol use.

TABLE 2—Standardized Regression Coefficients (Linear Multiple Regression Analysis) for Demographic Predictors in Past-Year Self-Reports of Use of Marijuana, Alcohol, and Cigarettes

Discussion

Although a low response rate severely limits the interpretation of these data, they are justified by the absence of similar published data for both gays and lesbians living outside major metropolitan areas.

Marijuana and inhalants were the most popular illicit drugs reportedly used by gay men in this sample. For lesbians, cigarette use is particularly alarming. Rates for current smoking among women in national health studies are approximately 20 percentage points lower than those found here.[22]

Although frequency of drug use among lesbians and gay men declined with educational level, frequency of alcohol use increased among gay men who are affluent, reside in urban areas, and have close interpersonal relationships. These factors did not significantly affect drug use among lesbians.

Prevalence rates for this sample can be examined in light of the prevalence rates found in the 1990 National Household Survey on Drug Abuse.[23] Among adults aged 18 to 25, 16.5% of men and 9.1% of women have used marijuana in the past month, compared with 37.5% of gay men and 23.5% of lesbians. Among adults aged 26 to 34, 73.7% of men and 55.2% of women have used alcohol in the past month; comparative figures for gay men and lesbians are 81.3% and 66.7%, respectively. Finally, among adults aged 35 and over, 27.1% of men and 22.0% of women reported smoking cigarettes in the past month, compared with 35.4% for gay men and 38.1% for lesbians. Clearly, illicit and licit drug use in the homosexual community is a public health concern requiring immediate attention. □

Breast Biopsy Rate and Positivity in Rhode Island

Margaret S. Richards, PhD, Judith Feldman, MD, MPH, Robert A. Smith, PhD, and Barbara A. DeBuono, MD, MPH

ABSTRACT

Breast biopsy is a common procedure for which few age-specific, population-based data are available. We identified all women who underwent breast biopsy in Rhode Island in 1989 by reviewing the specimen logs at each of 13 pathology laboratories. Among 425 000 women aged 15–97 years, 2685 underwent breast biopsy, for an overall rate of 6/1000. The rate increased with age, peaking among 45- to 54-year-olds and then declining in women over 75. Among those biopsied, 726 were diagnosed with breast cancer, for an overall biopsy positivity of 27%. In contrast to rate, positivity increased steadily with age. These results are within the range of estimates produced by smaller group studies. (*Am J Public Health.* 1994;84:1310–1312)

Introduction

In November 1987, the Rhode Island Department of Health, in collaboration with the Centers for Disease Control, initiated a Breast Cancer Screening Program. A review of data from the quality assurance component of this program raised questions about the extent of presurgical workup performed before biopsy. Although a number of publications have addressed this issue,[1–3] the majority have come from centers with special interest and expertise in mammography.[4] To date, we are unaware of any population-based studies of the association between prebiopsy evaluation and breast biopsy outcome.

The Rhode Island Department of Health has undertaken a two-phase, population-based study of breast biopsy among Rhode Island women. Phase I, which is complete, involved identifying all female residents who underwent open breast biopsy in the state in the calendar year 1989. The purpose of this phase was to generate a sampling frame for Phase II, which involves abstracting medical record data for a sample of women undergoing biopsy to identify those lesions and those diagnostic pathways that consistently lead to a negative (potentially avoidable) biopsy. This paper summarizes the descriptive data obtained in Phase I on biopsy rates and positivity.

Methods

Definitions

An open breast biopsy was defined as the removal of breast tissue to provide a definitive histologic diagnosis. This definition excludes percutaneous or cytologic procedures such as fine needle aspiration, treatment of established breast cancer such as mastectomy, and other procedures involving the breast, such as breast

At the time of the study, Margaret S. Richards was with the Office of Disease Control, Rhode Island Department of Health, Providence, RI, and the Epidemiology Program Office, Centers for Disease Control and Prevention, Atlanta, Ga; she is now with Abbott Laboratories, in Abbott Park, IL. Judith Feldman is with the Division of Preventive Health Services, Rhode Island Department of Health. Robert A. Smith was with the Division of Cancer Prevention and Control, Centers for Disease Control and Prevention; he is now with the Medical Affairs Department, American Cancer Society, Atlanta, Ga. Barbara A. DeBuono is with the Rhode Island Department of Health.

Requests for reprints should be sent to Judith Feldman, MD, MPH, Division of Preventive Health Services, 3 Capitol Hill, Rm 403, Providence, RI 02908-5097.

This paper was accepted November 12, 1993.

reduction or reconstruction. A positive biopsy is defined as a biopsy resulting in the diagnosis of breast cancer.

Enrollment

Women were included in the study if they had breast tissue examined at one of 13 hospital-based pathology laboratories processing breast specimens in the state of Rhode Island. The 13 laboratories process all outpatient and inpatient specimens. Surgical specimen logbooks were reviewed for any entry labeled "breast," and a specimen number was obtained. The corresponding pathology report was read. Breast specimens obtained from males or from procedures other than open biopsy were excluded.

Data Collection

The information obtained for each woman included name, birth date or age, biopsy date, biopsy outcome (positive or negative), histologic outcome (e.g., infiltrating ductal carcinoma), and hospital code (1–13). Rates of biopsy were calculated by using 1989 Census Bureau population estimates as a denominator.

Results

Biopsy Rates

Among 425 000 women age 15 to 97 years, 2685 underwent open breast biopsy in 1989, for an overall biopsy rate of 6/1000. The rate of biopsy increased with age, peaking among 45- to 54-year-olds and then declining in women over the age of 75 (Figure 1). Seventy percent of the women biopsied were diagnosed as having a benign breast condition (fibrocystic disease accounted for 72% of these diagnoses). Four percent of the women had noninvasive cancer, whereas 23% had invasive cancers; in both categories, ductal carcinoma was the dominant histologic type. For 3% of the biopsies, the lesions involved malignant tissue that was not of breast origin.

Biopsy Positivity

Among 2685 women biopsied, 726 were diagnosed with breast cancer, for an overall biopsy positivity of 27%. Positivity increased steadily with age, so that 75% of the biopsies performed on women age 85 and over revealed cancer (Figure 2). This steady increase with age in biopsy *positivity* is in contrast to the increase followed by a decline in biopsy *rate*.

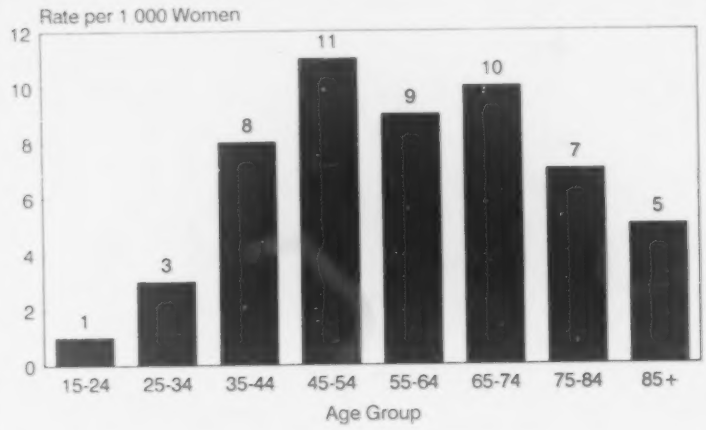

FIGURE 1—Breast biopsy rates by age, Rhode Island, 1989.

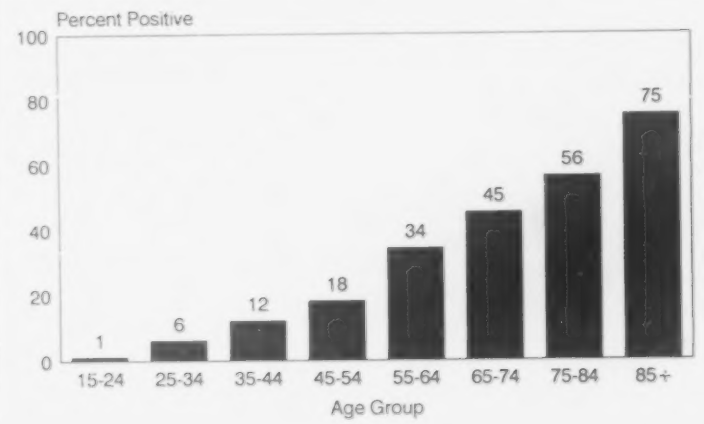

FIGURE 2—Breast biopsy positivity by age, Rhode Island, 1989.

Discussion

Efforts to achieve a consensus on the ideal breast biopsy positivity ratio have been hindered, in part, by a lack of population-based data on this procedure. However, some patterns emerge from these data that are in agreement with other studies. The overall biopsy positivity of 27% in our clinically heterogeneous group of women appears to be consistent with previous estimates. In other series,[3,5] positive biopsy percentages ranged from 9% to 65%, with a 15% to 30% positive biopsy rate among asymptomatic women[16] and a 20% to 40% rate among symptomatic women.[17–19] Our finding that fibracystic disease accounted for 72% of all the benign diagnoses is similar to that of a previous study.[20]

It is noteworthy that the older women (who are known to be at higher risk for breast cancer) have lower rates of biopsy but a higher rate of positivity in our study. The lower rate of biopsy may reflect a reluctance on the part of the patient or the surgeon to schedule a traumatic surgery unless the clinical suspicion of cancer is high (i.e., the woman is symptomatic). Cancer is more easily diagnosed in

the older, less dense breast, however—a potential factor in the increased positivity.

In Phase I of our study we essentially established a breast biopsy "registry" for the year 1989. A registry such as this one is population based if it includes Rhode Island residents biopsied out of state but excludes out-of-state residents biopsied in Rhode Island. Only a few of Rhode Island's hospitals include patient address on the pathology report, so we were unable to include residents diagnosed out of state and exclude nonresidents diagnosed in state.

We used the Rhode Island Cancer Registry to provide a proxy measure of breast biopsy referral bias in and out of state. In 1989, 926 cases of incident breast cancer were reported to the registry. Of these 926 cases, 29 (3%) cases were Rhode Island residents diagnosed in either Massachusetts or Connecticut and reported to Rhode Island through a reciprocal agreement. Fifty-five (6%) of the 926 cases were Massachusetts or Connecticut residents diagnosed in this state.

We theorize that most residents undergo biopsy in their home state, having been referred to a local surgeon by their primary care physician. If the biopsy is positive, a woman may choose to go out of state (e.g., Boston) for what she perceives to be specialist treatment. Because a positive biopsy is only one of several pathways to a cancer registry report, we assume that referral bias in our biopsy registry is minimal.

With these data, we are able to measure the parameters of biopsy rate and biopsy positivity and how these parameters vary across subgroups of age. After the completion of Phase II, we will be able to estimate how these parameters are mitigated by the family history of the patient and the clinical history of the patient, including symptomatology, histology, and prebiopsy diagnostic evaluation. □

Projected Numbers of Cancers Diagnosed in the US Elderly Population, 1990 through 2030

Anthony P. Polednak, PhD

ABSTRACT

As based on Bureau of the Census population projections and age-specific cancer incidence rates for 1985 to 1989 from the National Cancer Institute's Surveillance, Epidemiology and End Results program, the number of incident cancers diagnosed annually in the United States among persons aged 65 and over is projected to reach 1.5 million by the year 2030, or 2.4 times the number estimated for 1990. These projections, which may be conservative because birth cohort patterns (based on Connecticut rates) suggest possible future increases in incidence rates for all cancer sites combined, have implications for planning expanded primary prevention efforts, such as smoking cessation (especially for women) and dietary modification programs, and for projecting health care needs and costs. (*Am J Public Health.* 1994;84:1313–1316)

Introduction

Anticipated increases in the number of elderly persons in the US population in the coming decades, especially those aged 80 years and over, will result in increases in the numbers of incident cancers diagnosed.[1,2] This is especially true for cancers that tend to occur mainly in the elderly (e.g., those of the colon, rectum, pancreas, stomach, lung, bladder, and prostate).[1] This report uses available data on population projections and cancer incidence rates to estimate the total numbers of incident cancer cases that might be diagnosed in selected years between 1990 and 2030, and it discusses some implications of the projected increases.

Methods

Population projections were available from the US Bureau of the Census by age and sex; the middle series assumes constant fertility rates (with minor exceptions), slow increases in life expectancy, and constant net immigration.[3] Cancer incidence rates were obtained from the National Cancer Institute's Surveillance, Epidemiology and End Results (SEER) program, which includes nine population-based cancer registries (Connecticut, Hawaii, Iowa, New Mexico, Utah, Detroit, Atlanta, San Francisco–Oakland, and Seattle–Puget Sound) covering about 9.5% of the US population; these data are regarded as "reasonably representative" of the US population.[4] Rates were for all invasive cancers (along with in situ bladder tumors); leukemias and lymphomas were included.[4] SEER age- and sex-specific average annual incidence rates for all cancers diagnosed between 1985 and 1989 at ages 65 to 69, 70 to 74, 75 to 79, 80 to 84, and 85+ years[4] were multiplied by population estimates for the same age groups for each sex[3] for every fifth calendar year between 1990 and 2030. Projected numbers refer to cancers and not to numbers of patients with cancer.

Results

The numbers of incident cancers (all sites combined) are projected to increase more rapidly for men than for women in the next few decades (Table 1 and Figure 1). This is owing to greater predicted increases in the number of elderly men versus women in the US population, reflecting faster increases in men's life expectancy.[3] While the number of cancers diagnosed annually among persons aged 80 and over was slightly greater for women than for men in 1990, a crossover may occur by about 2010 (Table 1 and Figure 1).

After 2010, with the aging of the baby boom generation, the number of elderly persons will increase more rapidly than in previous years, resulting in larger increases in projected numbers of incident cancers. Percentage increases in the projected numbers of incident cancers per year, estimated every 5 years, were smaller from 1990 to 2010 than from 2010 to 2030.

Discussion

This study has several limitations. First, cancer rates for a broad age group were used for the oldest age category (85+ years) because data on cancer rates within this age group were lacking; this age group included 3.1 million persons (1.2% of the population) in 1990 and will comprise an estimated 8.4 million persons (2.4% of the population) in 2030.[3] Projected numbers of cancers in those aged 85 and over could be inaccurate owing both to rapid increases in incidence rates for certain cancers within this group and to greater increases in population size among the oldest ages. Second, if improvements in medical care (including cancer

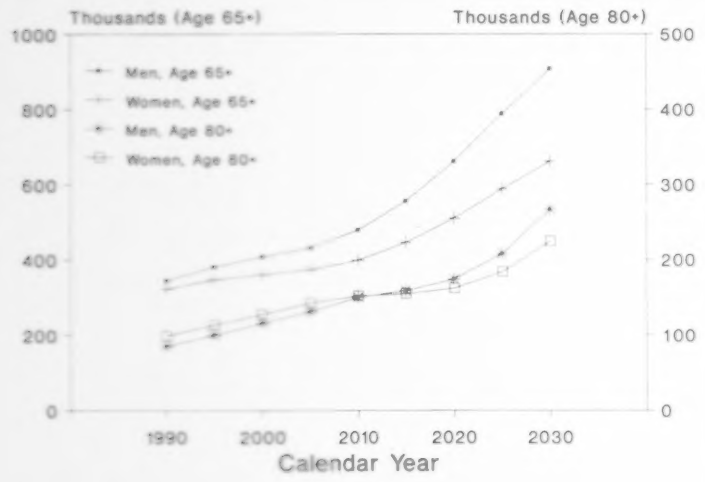

FIGURE 1—Projected numbers of incident cancers in the US population aged 65 and over and aged 80 and over, in selected calendar years.

treatments) result in faster increases in life expectancy than those assumed by the middle series of population projections, increases in the elderly population would be greater (as in the "high life expectancy" series)[3] than those assumed in this paper, and projected numbers of incident cancers would be greater than those in Table 1. Third, use of SEER rates probably resulted in a slight underestimation of incidence rates[5] and, hence, of projected numbers of cancers. The effect of projected increases in the proportion of minority members (e.g., Blacks, Hispanics, and Asians–Pacific Islanders) in the US population in the coming decades[1] was not considered, but it may be small. This is because cancer incidence rates have been higher for Blacks than for Whites[6] but lower for Hispanics (the fastest growing minority population), despite documented secular increases in cancer incidence rates in some Hispanic populations.[7]

In a 1984 report,[2] about 1.5 million cases of cancer for all ages combined were predicted for the year 2030; numbers for the elderly alone were not given.[2] The present analyses predict 1.5 million incident cases in 2030 for age 65 and over alone (Table 1); the projected number for all ages would be 2.1 million (data not shown).

Secular trends in cancer incidence and mortality rates often reflect birth cohort patterns because of cohort-related changes in exposure to carcinogens.[8–10] Birth cohort patterns were examined for Connecticut residents because cancer incidence rates in that state are available for years prior to the establishment of the SEER program in 1973 and rates for the elderly may closely approximate those for the entire United States.[5] Cohort patterns suggest that age-specific cancer rates (in 5-year intervals from ages 50 to 54 to ages 80 to 84) for all cancers combined in elderly men (Figure 2) and women (Figure 3) are unlikely to decrease—and could increase—in the next few decades. Thus, the projected numbers of cancers in the elderly (Table 1), based on the assumption of constant incidence rates over time, are probably conservative (i.e., underestimated), at least for the next few decades.

The latter conclusion is supported by the fact that few cancer sites have shown marked declines over time or across birth cohorts. Stomach cancer incidence rates have declined across birth cohorts (not shown), probably reflecting changes in diet[11] and exposure to specific bacteria,[12] but absolute rates were low by 1985 to 1989 (with no further decline in age-standardized rates in 1990–91), and these cancers have only a small effect on total cancer rates. For lung cancer, Connecticut incidence data (not shown) and US mortality data[13] indicate that rates, strongly influenced by sex- and cohort-specific smoking habits,[9,13–15] peaked for men born around 1925 to 1930 and for women born 10 years later and are declining in later cohorts (represented, as yet, only by nonelderly age groups). Any effect of declines in lung cancer rates (as post-1930 cohorts of men reach progressively older ages) on projected numbers of total cancers in elderly men, however, could be offset by future increases in incidence rates for prostate cancer (expected from birth cohort patterns). Even if some of the increasing numbers of prostate cancer cases detected by screening are "indolent" or clinically silent, these cases involve diagnostic procedures and often receive treatment.

The projected numbers of total incident cancers among women (Table 1) are probably conservative because women

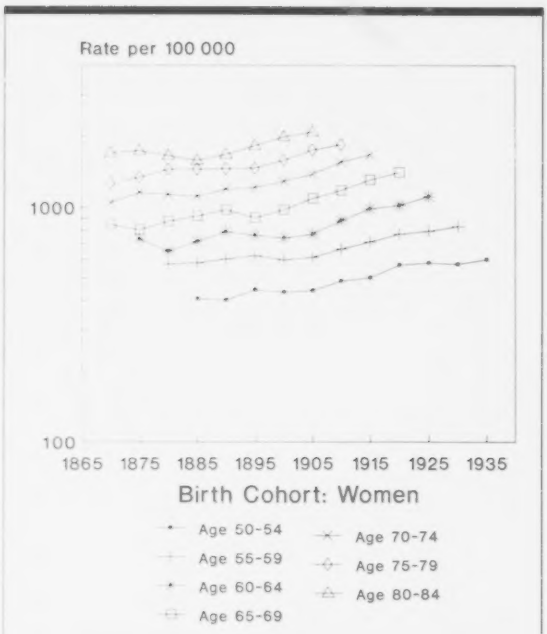

FIGURE 3—Age-specific average annual incidence rates per 100 000 women for cancers of all sites, by birth cohort (central year of birth) in Connecticut residents.

born around 1945 and later, for whom lung cancer incidence rates have started to decline, will not reach age 65 until 2010 (and will not reach age 80 until 2025). Although the use of breast cancer incidence rates for 1985 to 1989 in this study could be problematic because age-standardized incidence rates for invasive breast cancer increased more between that period and the 5-year interval preceding it than they did in previous periods (probably reflecting trends in screening), incidence rates for invasive breast cancer are not declining but are instead returning to a slower rate of increase like that evident in Connecticut since about 1940[8,16] and across birth cohorts until at least the 1955 cohort.[10]

Future studies should include projections of incidence rates by cancer site based on age-period-cohort modeling. The crude projections in Table 1 (and Figure 1), however, underscore the importance of primary prevention to reduce the impact of an aging population on the cancer burden. The birth cohort pattern for lung cancer incidence and mortality rates in women, along with evidence for higher risk in female than in male smokers,[17] supports the expansion of smoking cessation and prevention programs targeted to women.[18] A secular trend toward reduced fat intake may be occurring,[19,20] but intensifying efforts to reduce fat consumption and increase fruit and vegetable intake, as embodied in national objectives for the year 2000,[21,22] should eventually affect incidence rates for various cancers (as well as cardiovascular diseases) favorably, given the effects of antioxidant nutrients in certain foods (and nutritional supplements).[23] Along with chemopreventive effects of nutritional changes, progress toward national objectives for reducing alcohol and tobacco use[21,22] would decrease the risks for primary cancers of the aerodigestive tract and second primaries in patients with these cancers.[24]

The aging of the population was only a minor factor in the growth of health care costs from 1950 to 1987.[25] However, even if health expenditures increased only as fast as the general economy by 1996, the aging of the population (by itself) could cause health spending to reach 16% of the gross national product in 2030 (a 33% increase over the 12% in 1990).[26] There is increasing recognition of the need for studies of cancer treatment effectiveness in elderly cancer patients, who are often excluded from clinical trials.[1,27] While objective data on the cost-effectiveness of cancer treatment options in an aging population[28,29] are also being sought, equity (by age) in the receipt of effective cancer therapy should be the paramount goal, and patient preferences[30,31] cannot be ignored. □

Subsequent Hip Fracture among Older Adults

ABSTRACT

Subsequent hip fracture among the 368 Longitudinal Study on Aging respondents who fractured their hips from 1984 through 1991 was prospectively examined. Case-by-case review of the billing records indicated that 27 subsequent hip fractures occurred, for a rate of 1 every 33.8 person-years. Multivariable proportional hazard regression revealed that increased risks of subsequent hip fracture were associated with poor perceived health status and dizziness. (*Am J Public Health.* 1994; 84:1316–1318)

Fredric D. Wolinsky, PhD, and John F. Fitzgerald, MD, MBA

Introduction

Hip fractures occur frequently among older adults. Studies suggest that the lifetime risk of hip fracture is 6.0% for men and 17.5% for women.[1] Virtually all hip fractures require hospitalization.[2] Sequelae can include substantially reduced functional status or death.[3–5] Accordingly, a key target in federal health care policy is the reduction of the incidence of hip fracture in the elderly.[6]

Although research on the risk of hip fracture has increased,[7–11] little is known about subsequent hip fracture.[12] Indeed, there are no national studies of subsequent hip fracture. Accordingly, the purpose of this report is to prospectively assess the risk of subsequent hip fracture among the 368 Longitudinal Study on Aging respondents who were hospitalized for hip fracture from 1984 through 1991.[11]

Methods

Prior to our earlier report,[11] no comprehensive conceptual model of the

Note. The opinions expressed here are the authors' and do not necessarily reflect those of the funding agency, academic institutions, or government institutions involved.

risk of hip fracture existed. We classified the known and plausible risk factors associated with a first hip fracture into (1) ecological factors, (2) demographic factors, (3) social factors, (4) general health status, (5) symptoms and diseases conducive to hip fracture, (6) falling history and body mass, and (7) previous hip fracture. This sequence corresponds to a natural progression from the most distal to the most proximal risks, and it is consistent with the consensus that the most immediate risk factors are falling history, body mass, and prior hip fracture.[3,12,13] Although the risk of subsequent hip fracture may be dictated by a different process, initial reliance on the model developed for the first hip fracture is appropriate.

The data are taken from the Longitudinal Study on Aging, which is the follow-up to the Supplement on Aging appended to the 1984 National Health Interview Survey. The Longitudinal Study on Aging consists of the 7527 Supplement on Aging individuals aged 70 years or more in 1984 who were selected for follow-up interviews. Abstracts of the Medicare Automated Data Retrieval System, Part A (i.e., hospitalization), and National Death Index files are also available. We linked these files, identified the hospitalization episodes that contained the *International Classification of Diseases*, 9th edition, Clinical Modification (ICD-9-CM) codes for hip fracture (i.e., 820.0 through 820.9) in any of the five discharge diagnosis fields, and selected the first such episode from 1984 through 1991 for each Longitudinal Study on Aging respondent. These 368 individuals constitute our sample. Where multiple hip fracture billing records existed, we also selected all ensuing billings. These suggest subsequent hip fracture. Case-by-case review was then conducted to verify that these were actual subsequent hip fractures and not duplicate billings, same-day transfers to another hospital, or complications stemming from the first hip fracture. We used the unweighted Longitudinal Study on Aging data without adjustments for design effects[14–17] and the same variables we used in our analysis of first hip fractures.[11] These are defined and their means or percentages are provided in Table 1. To reduce bias due to overfitting or multicollinearity, all bivariate relationships between subsequent hip fracture and each independent variable were examined with a screening criterion of $P \leq 10$.[18] Cox proportional hazard regression was used. The date of the Longitudinal Study on Aging respondent's first hip fracture marked the beginning of the period of observation, and the date of subsequent hip fracture (censored at the end of the observation period—December 31, 1991) marked the end. Decedents were censored at the National Death Index date of their death. All analyses were performed with SPSS for Windows.[19]

TABLE 1—Independent Variables on the Risk of Subsequent Hip Fracture among the 368 Longitudinal Study on Aging Respondents Who Fractured Their Hips at Least Once, 1984 through 1991

Independent Variable	Mean or Percentage of Sample	Crude Rate Ratio with Subsequent Hip Fracture	95% CI
Ecological factors			
Rural residence[a]	37.2%	1.04	0.48, 2.24

Results

Of the 368 Longitudinal Study on Aging respondents hospitalized for hip fracture between January 1, 1984, and December 31, 1991, 51 had multiple billing records suggestive of subsequent hip fracture. Case-by-case review, however, revealed that 3 were duplicate

billings, 14 were same-day transfers, and 7 were rehospitalizations for medical or surgical complications from the first hip fracture. Thus, only 27 (7.3%) of these 368 respondents had subsequent hip fractures during the study period. This is the equivalent of one subsequent hip fracture every 33.8 person-years.

Table 1 contains the crude rate ratios (RRs). Only two variables met the screening criterion: poor (fair or poor vs good, very good, or excellent) perceived health (RR = 2.21; 95% confidence interval [CI] = 1.03, 4.72), and reported problems with dizziness (RR = 2.58; 95% CI = 1.20, 5.51). When advanced to the multivariable proportional hazards regression, neither variable had a statistically significant independent effect (poor perceived health: adjusted rate ratio [ARR] = 1.76; 95% CI = 0.80, 3.90; problems with dizziness: ARR = 2.18; 95% CI = 0.98, 4.83), although the equation was statistically significant, suggesting some collinearity between these two items.

Discussion

In this study we examined the risk of subsequent hip fracture among the 368 Longitudinal Study on Aging respondents whose Medicare Automated Data Retrieval System hospitalization records for 1984 through 1991 indicated that a hip fracture had occurred. Among these individuals, 27 subsequent hip fractures occurred, for a rate of 1 every 33.8 person-years. This rate is comparable to the 8% 5-year recurrence rate found in Rochester, Minn.[20] Respondents with poor perceived health and those who had trouble with dizziness had elevated risks for subsequent hip fracture. The association between poor perceived health and subsequent hip fracture mirrors that found for first hip fracture,[11] and it is consistent with a growing literature demonstrating perceived health's robust prediction of mortality and other adverse health events.[21–23] Although dizziness did not achieve statistical significance in our analysis of first hip fracture,[11] it has consistently been identified as a risk factor for hip fracture in previous studies.[1,3,12,13]

Although this report presents the first prospective analysis of the risk of subsequent hip fracture among a representative national sample of older adults, it is not without limitations. The three most important limitations are not knowing whether the subsequent hip fracture was on the same or the contralateral hip, sample size, and the length of the observation window. Only 368 respondents were at risk of having subsequent hip fracture and were at such risk for 8 years or less. Although the latter problem is not great (mean number of days to subsequent hip fracture = 613, to death without subsequent hip fracture = 674, and to censoring without subsequent hip fracture = 1132), further research on larger cohorts of those with hip fractures is needed to better characterize the risks associated with subsequent hip fracture. □

Lifetime Milk Consumption and Bone Mineral Density in Older Women

ABSTRACT

This study examined the relation between lifetime milk consumption and both axial and appendicular bone mineral density in 581 postmenopausal White women. Positive significant, graded associations between milk consumption in adulthood and bone mineral density at the spine, total hip, trochanter, intertrochanter, and midradius, but not the ultradistal wrist or femoral neck, were observed. Adolescent milk consumption showed similar, statistically significant associations (spine and midradius). Associations were independent of age, body mass index, years postmenopausal, thiazide, estrogen and alcohol use, smoking, and exercise. Regular milk consumption in youth and adulthood is associated with better bone mineral density at cortical and trabecular sites in elderly women. (*Am J Public Health.* 1994;84:1319–1322)

Introduction

Osteoporotic low bone mineral density often leads to fractures, costly hospitalization, and prolonged use of health services.[1] Milk accounts for about half of all dietary calcium intake in North America (B. Nowlin, California Dairy Council, telephone conversation, June 1993),[2] and the importance of calcium in milk for attaining peak bone mass[3,4] and preventing osteoporosis[5–7] may relate to the quantity consumed during specific life periods.[5,8–10] In this paper, we report the association of lifetime milk consumption with bone mineral density in a community-based cohort of older women.

Methods

Study Population and Data Collection

Between 1972 and 1974, 82% of adult residents of Rancho Bernardo, Calif, enrolled in a heart disease survey.[11] From 1988 to 1991, 84% (n = 624) of surviving, local, 60- to 79-year-old women from this cohort participated in a study of bone mineral density. All were ambulatory and provided written informed consent. The 624 women were administered a standardized interview to assess their medical and life-style history, including smoking history, estrogen and thiazide use, alcohol consumption, and exercise. A standardized food-frequency questionnaire[12] was used to assess the subjects' current dietary calcium intake and their calcium supplementation history. Participants also quantified their daily milk consumption during adolescence (12 to 19 years of age), midlife (20 to 50 years of age), and older adulthood (after 50 years of age) as (1) "rarely or never" (classified as none), (2) "about every week, but not every day" (low), (3) "1 to 2 glasses per day, about every day" (medium), or (4) "3 or more glasses per day, about every meal" (high). Childhood milk intake was not queried because of expected poor recall.

Height and weight were measured with women in light clothing without shoes; body mass index (weight divided by square of height [kg/m^2]) was calculated to estimate obesity. Bone mineral density of the lumbar spine and hip was measured by dual-energy x-ray absorptiometry. Bone mineral density of the ultradistal wrist and midradius of the nondominant arm was measured by single-photon absorptiometry.[13]

This analysis includes all 581 women who provided data on milk consumption history and had bone mineral density measurements.

Statistical Analysis

SAS was used for all analyses.[14,15] The Mantel-Haenszel test was used to identify linear trends in categorical variables by milk consumption history. Analysis of covariance was used in trend analyses of continuously distributed covariates and in site-specific calculations of mean bone mineral density levels by milk consumption category; adjustments were made for the confounding effects of age, body mass index, years postmenopausal, smoking history, current use of thiazides and estrogen replacement therapy, current exercise, and alcohol consumption. Very few women reported high milk consumption during midlife (n = 27) or older adulthood (n = 17); therefore, the medium and high categories were pooled for these age periods. Separate analyses were conducted in which calcium supplementation was stratified. All statistical tests were two-tailed, with statistical significance defined as $P < .05$.

Results

The average age of participants was 70.6 years, and all were White. The women had been postmenopausal for an average of 24 years. At the time of

Drinking alcohol 3+ days per week, %	48	43	39	27	.03
Taking calcium supplements, %	49	47	54	40	.57
Ever used calcium supplements, %	71	74	77	67	.27

Note. BMI = body mass index.

evaluation, 42% were using estrogen replacement therapy, 24% were using thiazides, 44% had never smoked, 71% exercised three or more times per week, and 43% drank alcohol more than three times per week. The mean total calcium intake was 1013 mg/day; 50% were currently taking calcium supplements.

As shown in Table 1, milk consumption declined with age. Only 19% of respondents reported that they drank no milk during adolescence, whereas 28% and 41%, respectively, indicated no milk consumption during midlife and older adulthood. More than 92% of women who drank little or no milk in adolescence drank little or no milk later in life. Milk intake in youth was inversely associated with smoking and positively associated with calcium supplements; no other variables were associated with teenage milk consumption. After adolescence, higher milk intake was associated with less smoking, less thiazide use, and more exercise, and after 49 years of age, higher intake was associated with less frequent alcohol consumption. Current use of estrogen or calcium supplements was not significantly associated with milk intake.

Figure 1 shows that higher milk consumption in adulthood was independently and significantly associated with higher bone mineral density levels at the midradius, spine, total hip, intertrochanter, and trochanter. Higher teenage milk intake was associated with significantly higher bone mineral density at the spine and midradius. Milk intake was not associated with bone mineral density of the ultradistal wrist. Analyses stratified by calcium supplementation revealed similar patterns (data not shown).

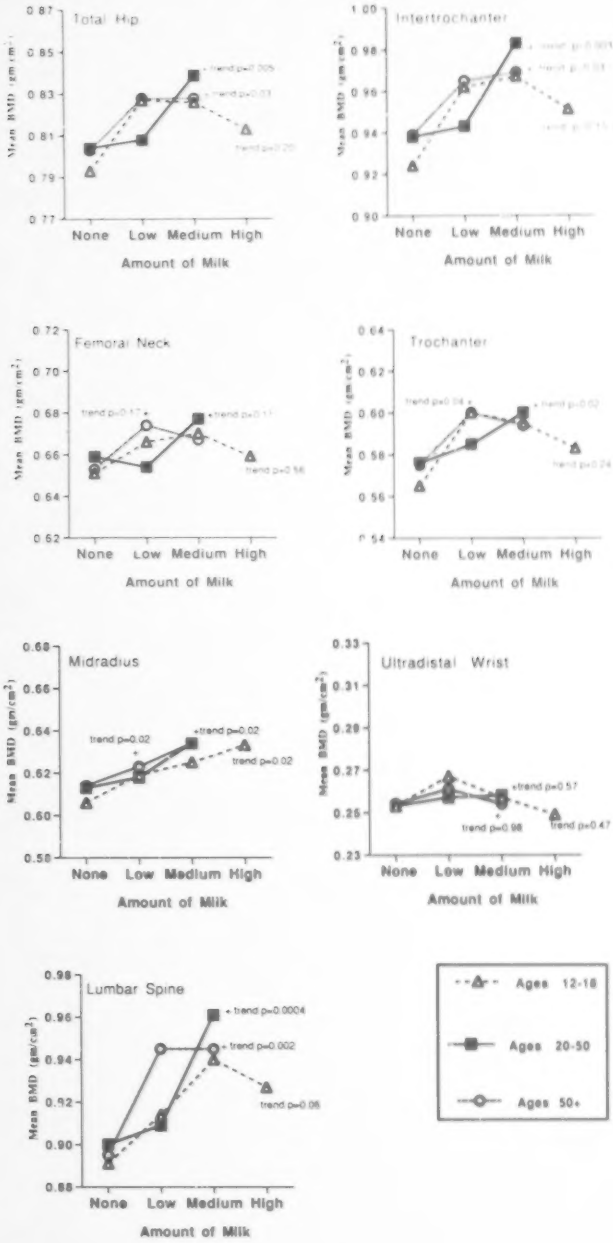
Discussion

Graded, significant associations between milk intake during three age periods and bone mineral density of the axial and appendicular skeleton were observed. These associations, independent of other major bone mineral density determinants, were strongest for milk intake during midlife (20 to 50 years of age).

The observed relation between bone mineral density and postadolescent milk consumption is consistent with evidence that a calcium-rich diet during adulthood contributes to peak bone mass[3,4,16] and/or helps minimize bone loss.[17-19] The weaker association of adolescent milk consumption with bone mineral density may reflect less variation in intake (adults have greater independence in beverage choices), inaccuracies of longer recall, or the lower per capita milk consumption during the Great Depression, which coincided with many participants' adolescent years. Alternatively, it may reflect the fact that most members of this cohort were children or teenagers when vitamin D, which mediates the absorption of calcium,[5] was first added to the US milk supply.[20]

The somewhat weaker trends for the oldest adults may reflect the downward shift in milk consumption with age. High intake after 50 years of age consequent to awareness of personal osteoporosis status did not appear to be a factor, since the relation between milk consumption and bone mineral density was not altered when the 65 women with physician-diagnosed osteoporosis or nontraumatic fractures were excluded from analysis (data not shown). Some older women may have decreased their milk consumption for health reasons.

Although self-reported milk consumption over a period of 50 years or more cannot be validated, it is unlikely that misclassification accounts for the observed association; measurement error in observational studies tends to reduce or obscure a true association.[21] Reported intake was remarkably stable over time for those who reported that they did not drink milk, with a downshift in high



Note. Means were adjusted for age, body mass index, years postmenopausal, smoking history, thiazide use, current use of estrogen replacement therapy, exercise, and alcohol consumption. Analysis of covariance was used in these calculations. BMD was measured in gm/cm². The medium and high milk consumption categories were pooled because of the small sample size of the high category for the two oldest age groups.

FIGURE 1—Multiply adjusted mean bone mineral density (BMD), by milk consumption and age group: Rancho Bernardo, Calif, women (n = 581), 1988 to 1991.

consumption with age. The proportion reporting high milk intake closely resembles that reported in similar age categories by others.[10]

Milk consumption was not associated with bone mineral density of the ultradistal wrist. Although it is possible that bone mineral density at this site is unrelated to calcium intake, a more likely explanation for this absent association is that the very low bone mineral density at the ultradistal wrist reduced the range of variation and precluded detection of differences.

Recently, Heaney, after accounting for methodological limitations in studies with negative results, argued that the literature supports a strong positive role for calcium in the prevention of age-related bone loss in women.[6] The protective effects of high dietary calcium intake on radial and spinal bone mineral density observed in this study were very similar to effects reported elsewhere.[3,10,16–18,22–24] Although we have found no other studies of milk consumption related to bone mineral density of hip sites, our findings are compatible with a previous report from this cohort in which 24-hour calcium intake was inversely related to risk of subsequent hip fracture.[19] This study lends further support to the importance of milk in the preservation of bone in women. □

Attitudes toward Body Size and Dieting: Differences between Elderly Black and White Women

June Stevens, PhD, MS, Shiriki K. Kumanyika, PhD, MPH, and Julian E. Keil, DrPH

ABSTRACT

Eating restraint and body size perceptions of 404 White and African-American women 66 to 105 years of age (mean age = 73 years) were assessed by questionnaire. Compared with overweight White women, overweight Black women were 0.6 times as likely to feel guilty after overeating, 0.4 times as likely to diet, 2.5 times as likely to be satisfied with their weight, and 2.7 times as likely to consider themselves attractive. Among those who were not overweight, Black women were half as likely as White women to consider themselves overweight. Compared with Black women, White women perceived themselves to be larger and reported a lower ideal body weight. (*Am J Public Health.* 1994;84: 1322–1325)

Introduction

The prevalence of obesity in African-American women is approximately twice that in White women.[1,2] Although the causes of this high Black–White ratio remain unclear, differences between African-American and White women in the motivation or ability to lose weight are probable contributing factors.[3–6]

Several researchers have reported differences in perceived or ideal body size in adolescent and college-aged African-American and White females.[5,7,8] Adult African-American women have also been shown to be less likely to think that being overweight is a problem[9] or to perceive themselves as overweight.[10] National data on the prevalence of weight loss attempts indicate that dieting patterns are similar among overweight African-American and White adult women and that, among women who are not overweight, dieting is less common in African Americans than in Whites.[10–14]

The purpose of this research was to examine attitudes toward eating and body size perceptions in elderly Black and White women. Reports of body size perceptions and eating restraint in elderly women are rare.[14] These attitudes, however, are relevant to older people in that they may influence the effectiveness of dietary interventions, including advice to lose or gain weight. Also, it is of interest to document attitudes toward eating and body size perceptions in Black and White women born at the turn of the century because there has been a secular change in societal pressures for thinness in American women.[15–18]
